Dormancy Breaking and Germination Requirements of Nimble Will \textit{(Muhlenbergia schreberi Gmel.)} Seeds

JERRY M. BASKIN AND CAROL C. BASKIN

Abstract

Nimble will \textit{(Muhlenbergia schreberi Gmel.)}, a native warm-season or 
C_{4} grass, is a serious weed in horse pastures in the Bluegrass Region of Kentucky. This study investigated the dormancy breaking and germination requirements of this species. Seeds mature in October, are dispersed mostly during autumn and winter, and germinate in spring. Seeds were dormant at maturity, but they became nondormant during (1) dry storage in the laboratory, (2) 99 days of incubation on moist sand at 35/20° C, or (3) cold stratification. Germination percentages were higher in light than in darkness, and cold stratified seeds germinated to higher percentages than dry-stored seeds. Seeds sown in a nonheated greenhouse in autumn were cold stratified during winter, and they germinated in spring when temperatures became nonlimiting. However, seeds that remained on the parent plants in the field over winter did not gain the ability to germinate at spring temperatures (20/10° C) by spring. Under some test conditions, the intact palea and lemma inhibited germination, but under other conditions they were not inhibitory.

Nimble will \textit{(Muhlenbergia schreberi Gmel.)} is a native warm-season or \C_{4} grass whose geographical range extends from southern Ontario and New England to northern Florida, westward to Iowa and central Texas (Pohl 1969, Dore and McNeil 1980). The original habitat of the species was light shade of moist forests (Pohl 1969), but it also now is common in lawns, waste places, and other disturbed habitats (Pohl 1969, Swink and Wilhelm 1979). Nimble will is the weedy species in the subgenus \textit{Muhlenbergia} (Pohl 1969), and Holm et al. (1979) list it as a common weed in the USA. Nimble will is the weediest species in the subgenus \textit{Muhlenbergia} (Pohl 1969), and Holm et al. (1979) list it as a common weed in the USA. In Kentucky the species is a weed in pastures and hay crops (Palmer 1979). However, aside from general information given in various taxonomic works, only a few scattered references on this species have been found in the literature.

Nimble will is a serious problem in horse pastures in the Bluegrass Region of Kentucky, where Kentucky bluegrass \textit{(Poa pratensis L.)} is the preferred grass (J.K. Evans, pers. comm.). The species is unpalatable to horses, and thus its presence decreases the grazing quality of the bluegrass pastures. Additionally, nimble will-infested pastures are unsightly from autumn to spring, when the species shows up as dead patches of green in the bluegrass sod.

In view of the importance of nimble will as a weed in horse pastures in central Kentucky and the paucity of information on the species, we are undertaking a study of its life cycle biology. This paper reports on the dormancy breaking and germination requirements of nimble will seeds. A knowledge of when seeds germinate and what environmental factors break dormancy and promote germination will aid in planning a successful management strategy for this species.

Nimble will is a hemicyrptophyte (Ennis 1928, McDonald 1937, Gibson 1961) with weak, slender sprawling culms that fall over and root at the nodes. The plants lack true stolons or rhizomes. In July, buds are initiated at the basal nodes of the culms. These buds give rise to new culms, which grow to a length of 1 to 5 cm by the beginning of winter. The new culms remain green during winter but do not elongate. Growth of the culms resumes in early spring, and by July they are fully elongated. Plants flower in August and September, and seeds are mature by late October. Seeds remain attached to the mother plant at maturity, and most of them are dispersed during autumn and winter.

Methods

The first objective was to determine when nimble will seeds would germinate in a nonheated greenhouse, where temperatures were near those out-of-doors (Baskin and Baskin 1981). Mean daily maximum and minimum weekly temperatures for the duration of the study were calculated from continuous thermograph records. Freshly matured caryopses (hereafter called seeds) were collected on 21 October 1981, and 7 days later 3 replications of 300 seeds each with the palea and lemma (hulls) intact were sown on soil in small flats. The soil was watered daily, except when frozen in winter, until the study was terminated on 18 May 1982. The flats were examined for seedlings at 7-day intervals.

Objective two was to test the temperature and light requirements for germination of seeds exhumed after 0 to 12 months of burial in soil. Seeds were collected on 21 October 1981, and 7 days later about 3,000 were placed in each of 12 fine-mesh nylon bags. Each bag was buried to a depth of 7 cm in soil in a 15-cm-diameter clay pot. The pots were kept in the nonheated greenhouse and watered daily, except when frozen. Germination tests were conducted on fresh seeds and on those that had been buried for 1 to 4 months. We originally planned to exhume seeds each month until November 1982. However, many of the buried seeds germinated in the soil in March 1982, so the experiment was terminated. Germination tests were performed in incubators at a 14-h photoperiod \textit{(ca. 20 \text{umol m}^{-2} \text{s}^{-1}, 400-700 \text{nm})} and in constant darkness at \textit{(12/12 h) alternating temperature regimes of 15/6, 20/10, 25/15, 30/15, and 35/20° C. Seeds were incubated on moist sand in 5.5-cm petri dishes. For dark-incubated seeds, 3 dishes of 50-75 seeds were placed at each temperature, and for light-incubated seeds 3 dishes of 50 seeds were used. Dishes incubated in darkness were wrapped with 2 layers of aluminum foil, and all manipulations of dark-incubated seeds were carried out in total darkness. Germination percentages were determined after 15 days.

Objective three was to determine the effects of cold stratification on germination of seeds with and without hulls. Seeds were collected on 7 November 1982, and studies were initiated 4 days later. Seeds were placed on moist sand in 5.5-cm petri dishes, and 3 replications of 50 seeds each were used for each treatment. Seeds with and without hulls were given 3, 6, and 9 weeks of cold stratification at 5°C in light \textit{(14-h daily photoperiod, 20 \text{umol m}^{-2} \text{s}^{-1}, 400-700 \text{nm})} and then tested in light at 15/6, 20/10, 25/15, 30/15, and 35/20°C. Also seeds stratified for 12 weeks in light were incubated in light and darkness at the 5 thermoperiods, and those stratified for 12 weeks in darkness were incubated in light and darkness. Germination percentages were determined after 15 days of incubation. In one set of controls, fresh seeds with and without hulls were placed in light and darkness at the 5 thermoperiods. After 15 days the seeds were examined, and those tested in darkness were discarded. Seeds tested in light were kept at their respective incubation temperatures until the experiment was terminated 12 weeks later. They were examined at 15-day intervals. In the second control, seeds with and without hulls were placed in closed bottles in the laboratory \textit{(ca 22-25° C)}. After 3, 6, 9, and 12 weeks of storage, seeds were incubated in light for 15 days at the 5 thermoperiods. After 17 weeks of storage, seeds also were tested in darkness at all thermoperiods. Germination percentages of seeds...
with and without hulls at each test condition were compared using Student's *t*-test at the 5% level of significance.

Objective four was to determine if seeds that remain on the
parent plant all winter become nondormant. On 23 March 1982,
seeds produced in 1981 were collected from plants in the field, and
their germination with and without hulls was compared to that of
seeds stored dry with and without hulls in the laboratory since 21
October 1981. Seeds were incubated in light and darkness for 15
days at the 5 thermoperiods. The least significant difference for all
germination percentages at each thermoperiod was computed
using Tukey's Honestly Significant Difference test (HSD) at the
5% level of significance.

Results and Discussion

Freshly matured seeds of nimble will were dormant and thus did
not germinate in light or darkness at any thermoperiod (Fig. 1c, d).

During winter, seeds exposed to natural temperatures in the non-
heated greenhouse lost their dormancy (afterripened). Seeds sown
on soil in the greenhouse in October began to germinate in mid
March and continued to germinate until mid May (Fig. 1b). A total
of 149 (39%) of the 390 seeds germinated. The peak of germination
occurred between 15 March and 5 April, when mean daily
maximum and minimum temperatures were 19.5 and 5.5°C, respec-
tively (Fig. 1a). In March, exhumed seeds germinated to 5, 54, 82,
77, and 73% in light at 15/6, 20/10, 25/15, 30/15, and 35/20°C,
respectively, and to 0, 31, 20, 24, and 16%, respectively, in darkness
(Fig. 1c, d). Since seeds exhumed on 1 March germinated to 31% at
20/10°C in darkness, it is not surprising that many buried seeds
germinated in the nonheated greenhouse during March.

Seeds of nimble will do not require cold stratification to after-
ripen (Fig. 2). Control seeds with and without hulls kept on moist

sand at 35/20°C germinated to 99 and 100%, respectively, during
the 99-day incubation period. Also, seeds with and without hulls
stored dry in the laboratory for 12 weeks germinated to 65 and
81%, respectively, at 35/20°C in light. However, with only 3 excep-
tions, at 20/10 and 25/15°C, seeds with and without hulls stratified
for 3, 6, 9, and 12 weeks at 5°C germinated to higher percentages at
all thermoperiods than seeds with and without hulls stored dry in
the laboratory for 3, 6, 9, and 12 weeks. Light was required for a
high percentage of the seeds to germinate, and light given during
stratification did not promote germination of seeds subsequently
incubated in darkness. For each treatment and control, germina-

tion percentages of seeds incubated in light tended to increase with

temperature.

Since most nimble will seeds are dispersed in autumn and winter,
they are cold stratified during winter. Thus, they are nondormant
by early spring and germinate when temperatures become nonlim-
iting. Seeds that were not dispersed during autumn and winter
germinated to only 5% at spring (20/10°C) temperatures in spring
(Table 1). In order for seeds to be cold stratified, they must be
imbibed, so undispersed seeds must have been dry (non imbibed)
for much of the winter.

Nimble will seeds without hulls germinated to a significantly
higher percentage than those with hulls in 14 of the 70 laboratory
tests (Fig. 2). In many species of grasses, the presence of hulls has
been shown to inhibit germination by restricting the diffusion of
gases (Vose 1965, Mott 1974, Renard and Capelle 1976), mechan-
ically restricting embryo growth (Andersen 1953, Martin 1975) and
the presence of inhibitory chemicals (Ahring, Eastin and Garrison
hulls were inhibitory to germination in nimble will, while under
other test conditions there was no significant difference in germina-
tion of seeds with and without hulls. The role of hulls in regulating
germination of this species in the field is unknown. However, hulls
were still on the seeds of nimble will that germinated in the non-
heated greenhouse.

Studies on the germination of sand muhly (Muhlenbergia are-
Jackson 1928, Toole 1938, Ashley and Hellmers 1955, Knipe and Toole 1938), purple muhley (M. Wrightii) and upland wild timothy (M. racemosa (Michx.) B.S.P.) (Toole 1938), purple muhley (M. rigens (Benth.) Hitchc.) (Toole 1938) and spike muhly (M. wrightii Vasey) (Sabo et al. 1979) indicate that they germinate well at high (20/30, 20/35, 25°C) temperatures, as do seeds of nimble will. In bushy muhly, purple muhly and upland wild timothy, 14 days of chilling had no effect on germination (Toole 1938). However, in none of these studies were the storage conditions of the seeds given. Thus, we must assume that seeds of these 5 species of *Muhlenbergia* were either nondormant at maturity, or, more likely, they were dormant at maturity and afterripened in dry storage, as do seeds of nimble will.

The fear by thoroughbred farm owners and managers that herbicides will do harm to their horses precludes the use of herbicides in most bluegrass pastures. Thus, control of nimble will is difficult. However, any seeds that are imbibed during winter will become covered by soil during winter. Although seeds stratified at natural temperatures during winter germinated to 31% when exhumed and tested at spring (20/10°C) temperatures in March (Fig. 2, dark). Spread of the species by seeds in a pasture could be prevented by not allowing plants to set seeds. Close mowing during flowering in August and September should reduce the number of seeds produced. Further, fertilizing pastures during the cool season would enhance the early growth of bluegrass, and thus increase its competitiveness with both seedlings and established plants of nimble will in spring.
