Root systems of two Patagonian shrubs: A quantitative description using a geometrical method

ROBERT J. FERNÁNDEZ A. AND JOSE M. PARUELO

Abstract

A method for mapping coarse root distribution suitable for stony soils was developed. Each root is considered as a broken line, whose segments are fairly straight root portions. The spatial location of end points of these segments is recorded in the field through 3 coordinates: its distance from plant vertical axis, its depth, and its distance to the foregoing point on the same root. With these data the roots' spatial arrangement is reproduced using a computer program including simple geometrical relationships. The main advantages of the method are: (a) it does not require sample harvesting and handling; (b) it considers root length instead of root biomass; and (c) its quantitative character allows statistically valid comparisons. Two species living in the Patagonian semidesert were studied: neneo (Mulinum spinosum, Umbeliferae) and mata mora (Senecio filaginoides, Compositae). In both shrubs, roots extend laterally more than 2 m and root length decreases exponentially as the distance from the canopy edge increases. Neneo was found to have its maximal root density at a depth of 0.4 m, whereas mata mora has most of its roots close to the soil surface. An interpretation of the differential response of these shrubs to grazing derives from these results.

Key Words: Mulinum spinosum, Senecio filaginoides, stony soil, Argentina

Our objective was to quantify the spatial distribution of roots of 2 woody species: neneo (Mulinum spinosum, Umbeliferae) and mata mora (Senecio filaginoides, Compositae). These species account for 76% of the woody cover and 19% of the total cover in the west, central Patagonia (R.A. Golluscio, unpublished data), with an estimated density of 1,200 and 1,900 plants/ha respectively (Fernández A. 1986).

To achieve this objective, it was necessary to develop a reliable method suited to the high stone content of the soil. At the same time, the procedure should not need excessive work, in order to allow replication and statistical inference.

Site Description

The study was carried out near the town of Rio Mayo (45°25'S Lat., 70°20'W Long., 500 m, Province of Chubut, Argentina) in a stand representative of the community of coirón amargo (Stipa speciosa and S. humilis), manuel choique (Adesmia campestris), calafate (Berberis heterophylla), and pasto hilo (Poa lanuginosa) (Golluscio et al. 1982) which is present on plateaus.

This arid steppe is dominated by 3 shrubs (neneo, mata mora and manuel choique) and by several tussock grasses (coirón amargo and coirón poa = Poa ligularis). Sheep graze year round on this type of vegetation, except for the summer months on farms with coirón blanco (Festuca pallescens) grasslands or wet valleys ("mallines").

Mean annual temperature is 7, 8° C (July: 2° C; January: 14° C). Average precipitation is 142 mm per year, 64% of which falls during the coldest season of April to September. Strong west winds blow during the whole year. The soil is a Calciorrhid (Golluscio et al. 1982). Gravel (>5 mm) accounts for 47% of its total weight. More detailed information about the environment and the 2 shrubs studied can be found in Soriano (1983) and Soriano and Sala (1983).

Materials and Methods

The variable considered in the development of this method was root length, which is judged to be a better index of root ability for water and nutrient uptake than root biomass (Böhm 1979). The method used is of a geometrical character. Each root and each ramification is considered as a broken line, whose segments are...
fairly straight root portions.

For each shrub species, 5 plants of modal size (A. H. Nuñez, pers. comm.) were sampled (Table 1). These individuals are encircled by a ring of tussock grasses (Soriano 1981). The distance between sampled shrubs and the nearest neighbor was not less than 1 m.

MD: maximum diameter; md: minimum diameter; H: height.

At the side of each plant a trench was dug in such a way that 2 of its walls joined with a 90° solid angle at the vertical axis of the plant. With origin in one of these walls, and with vertex in the center of the plant, a 45° horizontal angle was traced on the surface of the soil, defining an eighth of a cylinder around the plant, which was considered the sampling unit (Fig. 1).

With careful soil removal, the roots were exposed, and the spatial location of end points (Q) of each approximately straight root segment was recorded through 3 coordinates: its distance to the central axis of the shrub (DIST(Q)), its depth (DEPTH(Q)) and it distance to the foregoing point on the same root (LENGTH(P,Q)).

Fig. 1. Scheme of a sampling unit before root exposure.

From these data, it was possible to rebuild the 2 dimensional arrangement of roots through a 3-step algorithm (included in a BASIC computer program available from the authors):

a) Calculation of the length of each segment corresponding to each depth interval (VL(i)) (Fig. 2).

b) Calculation of the length of segment included in each horizontal distance interval (HL(i)) (Fig. 3).

c) Combination of the foregoing steps in such a way that the vertical and horizontal position of the segment is obtained. In other words, calculation of the length of the segment RL(i,j) located in each cell (i,j) of a 10 cm X 10 cm grid, re-building the 2 dimensional arrangement of the roots. (The horizontal origin of the pair of coordinates used as a reference is located at the center of the plant, and the vertical origin at the soil surface level.) This third step was considered necessary to avoid losing the interactions between the 2 dimensions which could be important in the interpretation of the roots' arrangement.

Analysis of covariance was applied to the data with total root length per plant as the covariate. Function adjustment was performed by regression analysis.

Results and Discussion

The method detected differences between the 2 species: two thirds of mata mora's root length was found in the first 40 cm of the soil in a radius of 1.50 m, whereas neneo shows the same proportion of its total root length in the 20-60 cm layer and in a circle of 1.20 m around the plant.

Compared with qualitative descriptions such as photographs or drawings, this method has the advantage of allowing statistical comparisons. Replication was possible since working in the 45°
sector reduced sampling time to about 6 hours per plant (trench digging excluded).

Maximum and average values of root density obtained here, around 100 and 1.4 cm/dm³ respectively, are lower than those observed by other authors in species from arid environments (e.g., Kummerow et al. 1978). This underestimation derives from the difficulty in detecting roots smaller than 0.5 mm in diameter, which have the greatest length per unit of biomass. However, we expect root spreading not to be affected by fine roots, since they would probably lack secondary growth.

Average root length was greater in mata mora (12,776 cm/plant; CV=32%) than in neneo (8,850 cm/plant; CV=55%); but the difference was not statistically significant. In both species, for each depth, root length followed a similar pattern with distance and, conversely, at each distance range the vertical pattern within a species remained unchanged. So, the analysis of root arrangement was made separately for each dimension.

The analysis of the horizontal distribution of roots revealed that the amount of roots under the projection of the shrub canopy is less than 50% of the total in both species, and that roots reach distances greater than 2 m (Fig. 4). Considering that woody individuals in this site average 3 m apart (Soriano et al., unpublished data), root spreading would be enough to allow some degree of overlapping between root systems of adjacent shrubs. Both species demonstrated a similar decrease in the amount of roots as the distance from the canopy edge increased (Fig. 4).

The vertical distribution of roots followed a different pattern in each species: whereas mata mora had most of its roots close to the soil surface, neneo showed its maximum concentration between 30 and 50 cm of depth (Fig. 5). The best fit was obtained with equations of a negative exponential type \( Y = 2897.8 e^{(0.019 \cdot \text{DEPTH})} \) and parabolic type \( Y = -363 + 79 \cdot \text{DEPTH} - 0.81 \cdot \text{DEPTH}^2 \), respectively. Significant differences between species were found in the upper layer (0–30 cm) and in a lower one (50–70 cm) (Fig. 5).

The soil of this community has a calcareous layer at 40 cm depth (Golluscio et al. 1982, Soriano and Sala 1983). Thus, most of mata mora's roots (73%) are between that stratum and the soil surface, and the most of neneo's were found included in the calcareous layer or near it. This would mean reduced overlap at lower depths with grass roots for neneo than for mata mora, since grasses have a large portion of their underground biomass in the upper 30 cm of the soil (Soriano et al. 1987).

These data allow an interpretation of the differential responses of the 2 shrubs to grazing in the community under study. Whereas mata mora increased its importance when sheep grazing pressure was high (Soriano 1956, Busacca 1981), neneo does not show a clear variation in its cover in response to range use (Busacca 1981). Browsing is minimal in these species (Bonvisuto et al. 1983). As grass biomass decreases under the effect of grazing, it may be expected that water and nutrient consumption by grasses also decreases. In this case, a greater supply of these resources would be available in the upper centimeters of soil, where mata mora has more roots (and supposedly more root activity) than neneo. In this situation, mata mora would be able to increase its biomass per plant or its number of individuals. In addition, the overlap of roots of grasses and mata mora would also have a temporal dimension since neither of them show a dormancy period (Soriano 1983).
