Influence of temperature on germination of Japanese brome seed

MARSHALL R. HAFERKAMP, DEBRA PALMQUIST, JAMES A. YOUNG, AND MICHAEL D. MACNEIL

Abstract

Japanese brome (*Bromus japonicus* Thunb.), an introduced annual grass, is now common in some northern mixed-prairie communities. This species has the potential to alter both the seasonality of standing crop and forage quality. We sought to gain a greater understanding of Japanese brome seed germination by subjecting seed to a series of 55 constant or alternating temperature regimes following 3 to 9 months of dry laboratory storage. Cold and moderate temperature regimes provided optimum germination conditions (defined as not lower than the maximum observed minus one-half its confidence interval at the 0.05 level of probability). Extremely cold or warm temperatures suppressed germination. Germination of afterripened seed over a wide range of temperature combinations, many of which occur during fall in the Northern Great Plains, should enhance establishment and perpetuation of Japanese brome on rangelands.

Key Words: *Bromus japonicus*, Great Plains

Japanese brome (*Bromus japonicus* Thunb.), an introduced weedy grass, has invaded some mixed-prairie communities in the Northern Great Plains (Haferkamp et al. 1993, Whisenant 1990). Its life cycle is short in comparison to coexisting perennial grasses like western wheatgrass (*Pascopyrum smithii* Rydb., (Love)). As with all annual grasses, Japanese brome herbage production is erratic from year to year (Hull and Pehanec 1947). Thus, presence of Japanese brome plants may shift the period of peak forage production, causing an earlier decline in overall forage quality (Cook and Harris 1952).

Perpetuation of Japanese brome depends on high seed production and propagation when environmental conditions are favorable. Determining temperature profiles for optimal germination of Japanese brome is one step in developing a better understanding of the population dynamics of this species. Understanding this phenomena is essential for developing effective schemes for managing Japanese brome infested rangeland.

Baskin and Baskin (1981) found Japanese brome seeds collected during August through November in south central Kentucky germinated nearly 100% during a 30-day incubation period in varying environments. Light conditions were either alternating (14/10 hours) light and darkness. Incubation temperature combinations of 12/11°C were 6115, 10120, 15130, and 20135°C which represented seedbed temperatures from late June until mid December.

In this study, we determined temperature profiles for germination of Japanese brome seeds collected in Montana during July and August and stored for 3 to 9 months. These seeds are representative of those disseminated during the period spanning late summer to early fall.

Materials and Methods

Japanese brome seeds were collected from native rangeland located on the Fort Keogh Livestock and Range Research Laboratory in Miles City, Mont. Collections were made on 10, 13, and 25 July and 2 Aug. 1990 and 12, 18, and 25 July and 1 Aug. 1991. Seeds were stored in paper sacks in the laboratory at about 21°C until germination trials were run in Reno, Nev., 3 to 9 months following collection. Seed was cleaned by hand in fall after all collections had been made each year. Storage or afterripening was of sufficient duration to remove primary dormancy reported for brome seeds collected in July (Hull and Hansen 1974, Baskin and Baskin 1981).

Four replications of 25 seeds from each collection date were incubated for 4 weeks in closed petri dishes on 1 mm thick filter paper moistened with distilled water. Dishes were arranged in a randomized-complete-block design, in 10 dark incubators. Constant incubator temperatures included 0, 2, 5 and all 5°C increments through 40°C. Alternating regimes were attained by moving dishes between incubators using 16 hours at each constant temperature plus 8 hours at all possible higher temperatures.
For example, 35°C was alternated with only 40°C, while 0°C was alternated with 2, 5, 10, 15, 20, 25, 30, 35, and 40°C. Germination counts were taken weekly, and seeds were considered germinated when the radicle was at least 5 mm long.

Data from each base temperature and its alternating temperature regime were used to develop regression equations of quadratic response surfaces with estimated germination means and confidence intervals at the 5% level of probability (Evans et al. 1982). A number of germination parameters were synthesized from these quadratic response surfaces (Young and Evans 1982) to assist in interpretation of germination temperature profiles. These included: mean germination, percentage of regimes with some germination, optimum germination, percentage of regimes with optimum germination, mean of optima, maximum germination, and frequency of optima (Young et al. 1992). The 8 quadratic equations consisted of the 4 collections made during 2 different years, 1990 and 1991. To determine if germination differences existed between accessions within a year and accessions between years, standard partial F-tests were conducted and resulting differences determined by nonoverlapping confidence intervals at the 5% level (Evans et al. 1982, Palmquist et al. 1987).

For presentation in tables, data were grouped into temperature regimes (minimum/maximum) that simulated natural seedbed environments occurring across a wide array of geographic locations based on seedbed monitoring studies (Evans et al. 1970, Evans and Young 1970, 1972, Young and Evans 1982). These temperature regime groupings are:

1. very cold (0/0, 0/2, 0/5, and 2/2°C);
2. cold (0/10, 0/15, 2/5, 2/10, 2/15, 5/5, and 5/10°C);
3. cold fluctuating (0/20, through 0/40°C and 2/20 through 2/40°C);
4. fluctuating (5/30 through 5/40°C, 10/35, 10/40, and 15/40°C);
6. warm (20/40, 25/35, and 25/40°C, 30/30 through 30/40°C, 35/35, 35/40, and 40/40°C).

**Results and Discussion**

Mean germination of Japanese brome seed from the 55-temperature profiles averaged across the 8 collection dates was 71±4.0%. Some germination occurred in 96±1.4% of the temperature regimes, and the mean germination for regimes where some germination occurred was 74±4.0%. Optimal germination (defined as germination not lower than the maximum observed minus one-half its confidence interval at 0.05 level of probability) occurred in 32±8.3% of the regimes, and the mean of the optima was 99±1.1%. The maximum observed germination was 100±0.4%. These findings suggest temperature does not appear to restrict germination once seeds are afterripened. Others have reported the temperature range favoring germination of many species narrows as dormancy intensifies and expands as dormancy declines (Vegis 1964).

Optimum temperatures for germination of Japanese brome seed were constant 20°C and alternating minimum/maximum regimes of 2-10/15, 0-15/20, 5-20/25, and 15/30°C (Table 1). Over 75% of the collections produced optimum germination in these regimes.

The partial F-test comparison of regression equations across both years (1990 and 1991) and collections (A, B, C, and D) leads to the conclusion that germination response to temperature regimes was not homogenous (P<0.01). Likewise, partial F-tests for collections A, B, C, and D for 1990 alone leads to similar conclusions (P<0.05) concerning the homogeneity of responses among collections within year and for 1991. Thus, there are germination differences between collections within a year and between the 2 years tested. Response surfaces developed for Japanese brome germination as a function of minimum and maximum incubation temperature treatments are given:

1 Estimated percent germination between year-by-collection-by-temperature regimes is not significantly different if followed by the same letter(s), as determined by overlap of their corresponding confidence intervals at $P<0.05$.

Germination was not attained. All others were similar to 1991 B where 100% germination was attained over several temperatures.

To determine where germination differences are occurring, confidence intervals for estimated mean percent germination for temperature regimes (Fig. 2) were derived from the response surface equation and compared (Table 2). Maximum germination of Japanese brome seed occurred at moderate and cold seedbed conditions with germination being somewhat depressed in very cold and warmer than moderate temperatures (Table 2). Although, differences existed between collections, in general responses followed similar trends between years.

A wide range of temperature conditions occur in fall on seedbeds in the Northern Great Plains region. Findings of this study suggest that while Japanese brome seeds collected in Montana are sensitive to temperature, germination in excess of 50% occurs over a wide range of temperature regimes. Thus, there is an excellent potential for continued invasion of this species on these Northern Great Plains rangelands. The high level of germination exhibited by afterripened Japanese brome seeds suggest a large portion of the disseminated seeds will germinate completely with available water during late summer and early fall.
