Tallgrass prairie vegetation response to spring burning dates, fertilizer, and atrazine

ROBERT B. MITCHELL, ROBERT A. MASTERS, STEVEN S. WALLER, KENNETH J. MOORE, AND LINDA J. YOUNG

Abstract

Tallgrass prairies provide an important source of hay and summer forage in eastern Nebraska. A study was conducted in 1989 and 1990 on 2 late seral tallgrass prairies near Lincoln and Virginia, Nebraska to determine if production of selected components of tallgrass prairie communities could be altered by burning (not burned, or burned in either early, mid-, or late spring) and applying fertilizer (0 and 67-23 kg N-P ha\(^{-1}\)) and atrazine [6-chloro-N-ethyl-N'-(1-methylethyl)-1,3,5-triazine-2,4-diamine] (0 and 2.2 kg a.i. ha\(^{-1}\)). Vegetation was harvested the year treatments were applied at about 30-day intervals starting in June and ending in August. Maximum big bluestem (Andropogon gerardii var. gerardii Vitman) accumulated standing crop (ASC) on unburned areas and areas burned in mid-spring occurred later in 1990 than in 1989. Burning in late spring 1989 maintained big bluestem ASC above 1,100 kg ha\(^{-1}\) through July, whereas big bluestem ASC declined below 840 kg ha\(^{-1}\) in July on areas where other burn treatments were applied. In 1990, big bluestem ASC exceeded 1,570 kg ha\(^{-1}\) in June on areas burned in early and mid-spring and exceeded 1,500 kg ha\(^{-1}\) in July on areas that were not burned or burned in mid- or late spring. From July to August 1990 big bluestem ASC declined below 730 kg ha\(^{-1}\) for all treatments except the late spring burn treatment where ASC was 1,540 kg ha\(^{-1}\). Burning in late spring reduced prairie dropseed [Sporobolus heterolepis (A. Gray) A. Gray] and tall dropseed [S. asper (Michx.) Kunth.] ASC by at least 67% in June 1990 compared to areas burned in early and mid-spring. Cool-season grass ASC at Virginia declined 86% in June when burned in late spring compared to areas burned in early or late spring. Cool-season grass ASC at Virginia declined 86% in June when burned in late spring compared to areas that were not burned. Fertilization increased big bluestem ASC by about 23 and 29% in June and July. Vegetation response to atrazine was variable. Atrazine had a negligible effect on big bluestem ASC. Burning late seral tallgrass prairie in late spring increased big bluestem ASC later in the growing season and decreased cool-season grasses more effectively than burning earlier in the spring.

Key Words: prescribed fire, nitrogen, warm-season grasses, Andropogon gerardii, Sorghastrum nutans, cool-season grasses, sedges.

Introduced cool-season forages and crop residues provide abundant spring and fall grazing for livestock enterprises in the central Great Plains. A need exists for high quality perennial forages during the summer (Krueger and Curtis 1979). This imbalance in seasonal forage supply limits the production potential of livestock operations. Warm-season grasses of properly managed tallgrass prairies can fill this gap in summer forage availability. Common warm-season grasses in tallgrass prairies include big bluestem (Andropogon gerardii var. gerardii Vitman), indiangrass [Sorghastrum nutans (L.) Nash], switchgrass (Panicum virgatum L.), little bluestem [Schizachyrium scoparium (Michx.) Nash], and sideoats grama [Bouteloua curtipendula (Michx.) Torr.]. In the central Great Plains, overgrazing has caused a shift in species composition from warm-season grasses to introduced cool-season grasses, Kentucky bluegrass (Poa pratensis L.) and smooth bromegrass (Bromus inermis Leyss.) (Wall and Schmidt 1983), and to a lesser extent undesirable warm-season grasses, prairie dropseed [Sporobolus heterolepis (A. Gray) A. Gray] and tall dropseed [S. asper (Michx.) Kunth.].

Fire and application of fertilizer and atrazine [6-chloro-N-ethyl-N'-(1-methylethyl)-1,3,5-triazine-2,4-diamine] can improve or maintain warm-season grass dominance in tallgrass prairies (Gillet et al. 1987, Masters et al. 1992). The response of tallgrass prairie vegetation to these treatments is influenced by factors including successional status (Gillet et al. 1987), date of burning (Anderson 1965, Towne and Owensby 1984), and date of fertilizer application (Rehm et al. 1976). Fire and fertilizer application have increased warm-season grass yields in Oklahoma (Graves and McMurphy 1969), Kansas (Owensby and Smith 1979), and Nebraska (Masters et al. 1992; Mitchell et al. 1994). Atrazine has been used to selectively control Kentucky bluegrass and smooth brome grass in established warm-season grass stands (Samson and Moser 1982, Waller and Schmidt 1983). Engel et al. (1990) determined that atrazine suppressed prairie threeawn in tallgrass prairies. They also found that combining burning with atrazine treatment did not improve prairie threeawn control and burning within 1 month before atrazine application decreased threeawn control. Atrazine applied 6 months after burning in late summer

The authors wish to thank Kevin Grams, Mark Dragastin, and Pat Spears for their assistance. We thank the Animal Sciences Dep., Univ. Nebraska, and Nine-Mile Prairie Committee for permission to conduct these studies at the Dutbev-Halleck Farm and Nine-Mile Prairie, respectively. Mention of a trade name in this paper does not constitute a recommendation by the Univ. Nebraska or the USDA-ARS nor does it imply registration under FIFRA. Contribution Number 10812 of the Agricultural Research Division, Univ. Nebraska-Lincoln, and the USDA-ARS. Manuscript accepted 21 May 1995.
did not increase grass standing crop in Oklahoma tallgrass prairies (Engle et al. 1993).

There is a lack of information on the influence of spring burning date or the combined effect of spring burning date, fertilizer, and atrazine on the yield of tallgrass prairie vegetation during the summer growing season. The objective of this study was to determine the effects of burning on different dates in the spring coupled with fertilizer and atrazine application on seasonal yield distribution of various vegetation components in late seral tallgrass prairies.

Materials and Methods

This study was conducted in 1989 and 1990 on late seral tallgrass prairies near Lincoln, Nebr. (Nine-Mile Prairie, University of Nebraska Foundation) and Virginia, Nebr. (Dalbey-Halleck Farm, University of Nebraska). Soils at Lincoln and Virginia were Shelby clay loam (Typic Arguidoll) and Pawnee clay loam (Aquic Arguidoll), respectively. The site near Lincoln had not been grazed since 1968 and had been burned in mid- to late April at 3 yr intervals. The site was also burned by a wildfire on 10 March 1988. The site near Virginia had been grazed during the summer each year since 1961. Livestock were excluded from the areas used for this study in 1989 and 1990. Since the early 1970’s, musk thistle (Carduus nutans L.) has been controlled at or adjacent to each site by annual applications of 2,4-D [2,4-dichloro-phenoxy] acetic acid] and dicamba (3,6-dichloro-o-anisic acid).

Big bluestem was the dominant species at both sites (Table 1).

Table 1. Botanical composition of tallgrass prairies near Lincoln and Virginia, Nebraska.

Immediately prior to application of each burn treatment, fine fuel loads were determined by clipping all herbage to a 2-cm stubble height within a 0.25-m² quadrate randomly located within each whole plot. Herbage within each quadrate was separated into live and dead components, oven-dried at 60°C, and weighed. At Lincoln, the fine fuel load averaged 4,700 kg ha⁻¹ and was comprised of 0, 2, and 15% live plant tissue at time of early, mid-, and late spring burn dates, respectively. At Virginia, the fine fuel load averaged 4,000 kg ha⁻¹ and was comprised of 0, 9, and 28% live plant tissue at time of the early, mid-, and late spring burn dates, respectively.

Herbage was sampled 3 times from each site at about 30-day intervals beginning in mid-June and ending in August the year of treatment application. Vegetation was harvested within two 0.75-m² quadrats located within each subplot. Vegetation within each quadrat was clipped to a 2-cm stubble height, separated into selected categories, oven dried at 60°C, and weighed to determine dry matter production. Areas disturbed by previous sampling activity were avoided during quadrat placement. Vegetation was separated into the following categories: big bluestem; indiangrass; dropseeds (prairie and tall); other warm-season grasses (little bluestem; switchgrass, and sideoats grama); cool-season grasses; sedges; forbs; and dead vegetation.

Accumulated standing crop (ASC) was calculated to characterize vegetative productivity throughout the summer. June ASC was produced between growth initiation or burning and the June harvest. July ASC was produced between the June and July harvests. August ASC was produced between the July and August harvests.

Data were analyzed using the general linear model procedure.
Results and Discussion

Total annual precipitation was less than the 50-yr average at both sites in 1988, 1989, and 1990. Precipitation in 1989 and 1990 was 12 and 2% below normal at Lincoln, and 30 and 16% below the long-term average at Virginia, respectively (Fig. 1a and b). Seasonal distribution of precipitation differed between 1989 and 1990 at both sites. In 1989, precipitation was well below the long-term average for the entire growing season at Lincoln and Virginia. In contrast, precipitation was close to or exceeded the long-term average through the growing season in 1990.

Warm-Season Grasses

Big bluestem accumulated standing crop (ASC) was primarily influenced by date of burning and fertilization. The harvest date by burning date by year interaction and harvest date by fertilization interaction were significant (P<0.05), but interactions that included atrazine were not significant (P>0.20). Dates of greatest big bluestem ASC varied by year and date of burning (Fig. 2a). 

Big bluestem ASC in June 1989 did not differ significantly among burn treatments. In contrast, big bluestem ASC in July 1989 was greatest on areas burned earlier in late spring and was at least 40% greater than areas burned in the spring. In August 1989, big bluestem ASC became negative for each burn treatment. These negative values occurred because the rate of growth slowed to the point where herbage disappearance exceeded herbage accumulation.

Maximum big bluestem accumulated standing crop (ASC) for nonburned and mid-spring burned areas occurred later in 1990 than in 1989 (Fig. 2a). Accumulated standing crop on nonburned areas and those burned in mid- to late spring exceeded ASC on areas burned in early spring by about 50% in July 1990. By August 1990, big bluestem ASC on areas burned in late spring was at least 46% greater than ASC on other areas (Fig. 2a).

Time of maximum big bluestem accumulated standing crop (ASC) varied by year, but was successfully manipulated by altering date of burning in the spring. Burning in late spring 1989 maintained big bluestem ASC above 1,100 kg ha⁻¹ through July, whereas big bluestem ASC declined to less than 840 kg ha⁻¹ in July on areas where other burn treatments were applied (Fig. 2a). In 1990, big bluestem ASC exceeded 1,570 kg ha⁻¹ in June on areas burned in early and mid-spring and exceeded 1,500 kg ha⁻¹ in July on areas that were not burned or burned in mid- to late spring. From July to August 1990 big bluestem ASC declined below 730 kg ha⁻¹ for all treatments except the late spring burn treatment where ASC was 1,340 kg ha⁻¹. The difference in distribution of growth in 1989 and 1990 may be explained by the lower than average precipitation at Lincoln and Virginia in 1989 as compared to precipitation that was close to the average through much of the spring and summer of 1990. Increased precipitation in 1990 likely sustained big bluestem growth later into the summer than during 1989 when less precipitation was received.

Burning in late spring consistently shifted maximum big bluestem accumulated standing crop (ASC) later into the summer than the other treatments (Fig. 2a). Although soil water content was not measured during the growing season, delaying burning until late spring may have conserved soil water for use by big bluestem later in the growing season. The plant litter that remained on the site until burning in late spring likely protected the soil surface from desiccating winds, solar insolation, and damage to soil aggregation by raindrop impact (Anderson 1965). Another reason for the shift in big bluestem production could have been interruption and delay of tiller development caused by burning in late spring.

The positive response of big bluestem to burning has been observed by others. Burning substantially increased big bluestem production in Illinois (Old 1969), Kansas (Knapp 1985), Missouri (Kucera and Elsenritcht 1962), Nebraska (Masters et al. 1992), Oklahoma (Svejcar and Browning 1988), and Wisconsin (Peet et al. 1975). Svejcar (1990) indicated that species composition and timing of fire strongly influences the response of tallgrass prairie vegetation. Generally, burning in late spring benefits big bluestem, while adversely affecting grasses and forbs that emerge earlier in the spring than big bluestem.
Fertilization increased \((P<0.01)\) big bluestem biomass in June and July, but had little effect in August. When compared to non-fertilized areas, fertilizer increased big bluestem accumulated standing crop (ASC) 23 and 29\% in June and July, respectively. These results are consistent with studies in Oklahoma (Graves and McMurphy 1969) and Kansas (Moser and Anderson 1965) tallgrass prairies where increases in forage production were observed following N fertilization.

Prairie dropseed and tall dropseed comprised very little of the total vegetation at the Lincoln site, but accounted for as much as 11\% of that at the Virginia site (Table 1). Accumulated standing crop of the dropseeds in June was reduced \((P=0.03)\) to 370 kg ha\(^{-1}\) by late spring burning when compared to areas burned in early and mid-spring 1990 at Virginia (Fig. 2b). The caespitose growth characteristics of prairie dropseed, the dominant dropseed, made it more susceptible to injury by fires in the late spring. The centers of the plant bunches were comprised of compact dead tillers that were observed to smolder for an extended period of time after the passage of the fire front. Increased duration of exposure of meristematic tissue to heat probably injured viable tillers and suppressed yields in June and July following late spring burning. Other caespitose species generally respond negatively to late spring burning due to accumulation of litter within the plant crown, and are especially susceptible to fire injury when conditions are dry (Towne and Owensby 1984, Wright 1971).

Weaver (1954) described the dropseeds as highly drought tolerant species commonly found on upland prairie sites. He noted that the quality and palatability of these grasses rapidly declined as summer progressed. We observed that prairie and tall dropseed were not selected by cattle grazing areas adjacent to the research site at Virginia, which suggests that dropseed suppression may be a desirable management objective in grazed tallgrass prairies.

Indiangrass was influenced \((P=0.05)\) by the combination of spring burning date and atrazine application, but responses to specific treatments were variable. Mid-spring burning combined with atrazine reduced indiangrass accumulated standing crop (ASC) in August by 79\% compared to mid-spring burning with no atrazine (Table 3). Late spring burning combined with atrazine increased indiangrass ASC in August by nearly 9-fold compared to late spring burning with no atrazine.

Accumulated standing crop (ASC) of other warm-season grasses was influenced \((P=0.01)\) by spring date in 1989 and 1990. Other warm-season grass ASC in August 1989 was increased by

\(^1\)Averaged across sites, years, and fertilizer treatments.
burning in mid- and late spring (Fig. 2c). Drought conditions that persisted in 1989 may have caused increased senescence that resulted in negative ASC in August on areas not burned and areas burned in early spring. Burning in late spring 1990 increased the July ASC of other warm-season grasses to 490 kg ha⁻¹ when compared to not burning or burning in mid-spring.

**Cool-Season Grasses and Sedges**

The small contribution (<3%) of cool-season grasses to standing crop at Lincoln reduced our ability to discern treatment effects at that site (Table 1). Evaluation of treatment effects on this group of species was limited to the site at Virginia where cool-season grasses averaged at least 16% of the total plant herbage (Table 1). Burning in late spring reduced (P<0.01) cool-season grass ASC in June by 86% when compared to non-burned areas (Fig. 3a). This reduction could have resulted from removal of the top growth of the cool-season grasses and damage to the meristematic tissue at a time that usually coincides with peak production of cool-season grasses (Wall et al. 1986). Cool-season grass accumulated standing crop (ASC) was not affected by fertilization (P=0.11) or atrazine application (P=0.11).

Accumulated standing crop (ASC) of sedge species was greater at Lincoln than at Virginia, although sedges were a minor component at both sites (Table 1). Sedge ASC was affected (P<0.01) by early and mid-spring burning only in June at Lincoln (Fig. 3b), but was not affected by fertilization (P=0.59) or atrazine application (P=0.12). Burning in early or mid-spring increased sedge ASC in June by at least 187% compared to areas not burned and areas burned in late spring, but had no influence on ASC in July or August. Sedge ASC on areas that were not burned or burned in late spring was reduced at least 65% when compared to areas burned in early and mid-spring. Reduced sedge ASC in the areas not burned probably resulted from attenuation of light caused by litter accumulation. Burning in early or mid-spring removed litter before sedge shoot apices were elevated and susceptible to damage by the fire. Fire-induced litter removal opened up the canopy, which improved the light environment and sedge production. Knapp and Seastedt (1986) indicated that the massive amounts of plant litter that can accumulate in tallgrass prairies reduce the quantity and quality of light reaching emerging plant shoots. Reduced sedge ASC following late spring burning may have occurred because the apical meristems were elevated and consumed by the fire. Reduced ASC in July and August reflected the increased maturity and senescence of the cool-season sedges.

**Forbs**

Sampling methods used in this study apparently were not sufficiently sensitive to accurately assess the impact of the various treatments on the forb component of the prairie communities. The history of application of the broadleaf-specific herbicides, 2,4-D and dicamba, to control musk thistle at or near the sites at Virginia and Lincoln probably reduced forb abundance and richness.

**Conclusions**

Date of spring burning influenced the quantity and distribution of tallgrass prairie vegetation production during the summer more than fertilizer or atrazine. Burning in late spring increased big bluestem accumulated standing crop later in the growing season and decreased cool-season grasses, prairie dropseed and tall dropseed. Fertilization increased the quantity of big bluestem, but vegetation response to fertilizer was more variable than response to burning date. Atrazine had negligible or variable effects on tallgrass prairie vegetation. Atrazine does not appear to be a useful tool to improve warm-season grass forage production in late seral tallgrass prairies. This is fortunate since atrazine is no longer registered for use on rangeland or pastures.

This study provides evidence that the quantity of big bluestem available during the summer can be manipulated by burning on different dates in the spring. Increasing the quantity of big bluestem present in late summer could have a positive effect on performance of livestock grazing tallgrass prairies dominated by big bluestem and alleviate seasonal forage imbalances common to the central Great Plains. A possible management scenario could be to burn tallgrass prairie pastures at different dates during...
the spring. We suggest that a firm could burn some pastures in early spring to increase late spring forage availability, burn other pastures in mid-spring to increase mid-summer forage availability, and burn the remaining pastures in late spring to improve forage availability in mid-to late summer.
