Recovery of leafy spurge seed from sheep

BRET E. OLSON, ROSEANN T. WALLANDER, AND RODNEY W. KOTT

Abstract

Sheep are often used to graze North American rangelands infested with leafy spurge (Euphorbia esula L.), a long-lived perennial forb from Eurasia. Our objective was to determine if sheep grazing infested rangelands disperse leafy spurge seed by transport in their fleece or by depositing seeds in their feces. Twenty-four yearling Targhee ewes grazed a 2.4 ha native bunchgrass range site infested with leafy spurge from late-May through mid-August of 1993 and 1994. Six of the 24 ewes were shorn in October 1993. To recover leafy spurge seeds from those fleeces, we used a standard method to test wool for vegetable matter. On average, 38 seeds were recovered per fleece. During these summers, 6 small groups (n = 4 sheep per group) each grazed 3 separate paddocks. We estimated the density of leafy spurge seed before the groups were moved into 1 of 3 paddocks. After the sheep were moved into a paddock (day 0), we collected fresh feces from each group on or about day 4, 10, and 14. Feces were then washed over sieves to recover leafy spurge seeds. All seeds were tested for germinability and viability. The number of viable seeds excreted daily per ewe was estimated. In 1993, 1,796 ± 405 (S.E.) leafy spurge seeds m⁻² were produced in the field, whereas in 1994, 399 ± 63 (S.E.) leafy spurge seeds m⁻² were produced. The summer of 1994 was much drier than the summer of 1993. We estimated that 41 to 144 leafy spurge seeds were excreted daily per animal in mid-July 1993. Viability of seeds in the feces averaged 5%, whereas viability of seeds collected from seed stalks was 42%. We estimated that the ewes excreted from 2 to 41 leafy spurge seeds daily at the peak in mid-July 1994. Viability of seeds excreted during 1994 averaged 24%, whereas viability of seeds collected from seed stalks was 68%. Sheep can pick up leafy spurge seed in their fleece, and will consume and pass viable seed. However, viability of seed recovered from feces was highly variable and almost always lower than seed collected in the field. Despite reduced seed numbers and viability, sheep have the potential to spread leafy spurge and should be managed accordingly.

Key Words: weeds, feces, fleece, seed dispersal.

Leafy spurge (Euphorbia esula L.) is a perennial Eurasian forb that was first discovered in North America in 1827 (Selleck et al. 1962). This plant is considered noxious and currently infests over 1.1 million ha in the Northern Great Plains of the United States and Prairie Provinces of Canada (Lacey et al. 1985). Chemical control of leafy spurge is not cost-effective for most native rangelands (Lym and Messersmith 1987). Biological control with insects shows some promise, especially if it is integrated with herbicides (Lym 1994). This plant has had a major impact on the economy of North Dakota (Thompson et al. 1990).

Sheep and goats will graze leafy spurge and can be used to control infestations (Lacey et al. 1985). However, when sheep graze leafy spurge during the mature seed stage, seeds may become embedded in their fleece when seeds dehisce from capsules (Bakke 1936). Sheep also may pick up seed from the soil surface on bedgrounds. In the past, numerous plant species were introduced to Europe via sheep fleeces (Ridley 1930). Also, sheep on Utah rangelands pick up and presumably disperse capitula of squarrose knapweed ([Centaurea virginia Lam. var. squarrosa (Willd.) Boiss]; Roche and Roche 1992).

Sheep consuming leafy spurge seeds may also disperse viable seeds in their feces (Harmon and Keim 1934, Lehrer and Tisdale 1956, Özer 1979, Thill et al. 1986, Simao Neto et al. 1987, Dastgheib 1989). Viability of seed recovered from feces may be enhanced or reduced compared with seed that has not passed through sheep (Harmon and Keim 1934, Lacey et al. 1992, Wallander et al. 1995). Germinability of seeds recovered from feces generally decreases as residence time in the gastrointestinal tract of sheep increases (Özer 1979, Lacey et al. 1992, Wallander et al. 1995).

Before capsules of leafy spurge dehisce, sheep grazing infested rangeland consume seeds in capsules that may protect seed from mastication, rumination, and other digestive processes (Wallander and Olson, unpublished data). In 1 study, sheep were dosed with a known amount of mature leafy spurge seed (Lacey et al. 1992); only 18% of the seeds was recovered in their feces within 9 days. Viability of those seeds was reduced compared with unfed seed. Our objective was to determine if sheep grazing leafy spurge-infested rangeland can disperse leafy spurge seed by picking up seeds in their fleece, or by ingesting and passing viable seed in their feces.

Materials and Methods

Our study site was located in Gallatin County in southwestern Montana (111°33' W 45°40' N) at 1,480 meters above sea level.
on northeast facing bluffs above the Madison River. Soils are classified as loamy skeletal mixed Aridic Calciborolls (USDA 1995). The rangeland cover type is Idaho bluebunch wheatgrass (Bakke 1936, Delorit 1970). Leafy spurge cover varied from 0 to 70% on the site. Seeds of leafy spurge are roundish oval, obovate in outline and circular in cross-section, 2.0-2.5 mm long, 1.3 to 1.5 mm wide (Bakke 1936, Delorit 1970). Depending on seed color, 100 leafy spurge seeds weigh from 182 to 302 mg (Wicks and Dercheid 1953).

At our study site, a 2.4 ha pasture was divided into 3 similar sized blocks. Each block was further divided into 2 lanes. One lane of each block was for a group of yearlings (n = 4) that had been exposed to leafy spurge as lambs (experienced), the other was for a group of yearlings (n = 4) that had not been exposed to leafy spurge as lambs (naive). All yearlings were Targhee ewes, averaging 55 kg. Their staple length at the beginning of summer was approximately 2.5 cm with a fiber diameter of 22-23 microns. Each lane was divided into 3 paddocks. These yearlings were rotated twice through these paddocks infested with leafy spurge from late May until mid-August in 1993 and 1994. From mid-August until early October 1993, a subset of yearlings were kept in a small, tame pasture that did not contain any leafy spurge before they were sheared for the fleece study.

Seed in Fleece

In October 1993, 6 of 12 naive sheep were shorn and these raw fleeces (grease) were weighed. Each fleece was tested for vegetable matter using standard methods (ASTM 1993). In this test, wool was compressed in a cylinder and 3 subsamples of 50 cores (1.3 cm diameter) were removed from each fleece. Subsamples were weighed and digested in concentrated sodium hydroxide for 1 hour before washing. Material retained by both sieves was collected, wrapped in paper towels, and dried at 37°C for 24 hours. Each fresh fecal sample was carefully inspected in the field, rinsed 3 times with deionized water. These plates were placed in cold storage until they could be examined for seeds. The accuracy of this procedure was tested by spiking each of 5 fecal samples with 30 mature seeds. All 30 seeds were recovered from each sample.

Statistical Analyses

Average leafy spurge seed production (m-2) in each lane was estimated for 3 sampling dates in 1993 and 1994, coinciding with when the sheep were moved into a new paddock and the beginning of a fecal collection period. The number of seed excreted...
daily per animal was estimated for 7 fecal sampling dates in 1993 and 1994. Least-square means of seed production and the number of seed excreted daily per animal were dependent variables in separate models. Collection period, block, and treatment (naive or experienced) were main effects with number of mature leafy spurge seed m⁻² in the field as a covariate (PROC GLM; SAS 1988). Collection dates were tested within collection periods. In a second model, percent viability was the dependent variable, and collection period, block, treatment, and class (seed recovered from feces or collected from field) were main effects. Percent viability data were transformed (arcsine square root) to prevent the dependence of the variance on the mean, which is inherent with data that have binomial distributions (Sokal and Rohlf 1995). We present nontransformed data in figures. Viable seed excreted daily per animal was derived by multiplying the estimated number of seed excreted daily per animal by percent viability of seed recovered from the feces that day.

Results

Seed in Fleece

On average, 38.7 leafy spurge seeds were found in each fleece (Table 1), although 3 fleeces did not contain any leafy spurge seed. Fleece weights were about 50% of normal because the ewes were shorn in October, 6 months earlier than normal.

Seed in Feces

In late June 1993, 1,796 ± 405 (S.E.) leafy spurge seeds m⁻² were produced in the field combining numbers of seeds in the different categories (Fig. 1a). Most of these seeds were in immature capsules. The proportion of mature seed collected from seedstalks increased as the summer progressed, although total number of seed decreased through the summer (P = 0.005). In 1994, 399 ± 63 (S.E.) leafy spurge seeds m⁻² were produced on 8 July (Fig. 1b). Most of the seeds were mature at this time. Total number of seed decreased through the summer (P = 0.005). Besides sampling later, 1994 was considerably drier than 1993 and thus the plants may have been more advanced phenologically.

mean = 38.7 ± 21.6 s.e.

At the peak, 144 leafy spurge seeds were excreted daily per animal on 17 July 1993 (Fig. 2a) More seeds were excreted during this third week of July than in the other periods (period effect, P = 0.05). The number of seeds excreted daily per animal was lower in 1994 than in 1993. It peaked at about 40 seeds on 11 July 1994 (period effect, P = 0.76, Fig. 2b). In 1994, the number of seeds excreted was lowest on the first sampling date shortly after they had been moved from the previous paddock, and highest 3–4 days later (collection date within period effect, P = 0.02).

In 1993, viability of seed recovered from fecal samples increased after mid-July (period effect, P = 0.001), yet it was always lower than seed collected from seedstalks (P = 0.0007; Fig. 3a). In 1994, viability of seed recovered from fecal samples was lower than seed collected from seedstalks (P = 0.0007), but there was no trend through the summer (period effect, P = 0.26; Fig. 3b). Overall, viability of seed recovered from fleeces was lower in 1993 than in 1994. Viable seed excreted daily per animal ranged between 0 and 17 in 1993 and 0 and 10 in 1994 (Fig. 4a, b).

Discussion

Sheep grazing leafy spurge infested rangeland collected seed in their fleece. However, we believe that the crimped nature of wool would result in seed readily adhering to wool fibers and becoming embedded. Unless the seed drops before it has a chance to

become embedded, it is unlikely that seed would be dispersed later. More likely, the seed would fall out during shearing or processing (Ridley 1930).

Seed in capsules collected from seedstalks did not germinate. When opened for the tetrazolium test, most of these seeds were empty or contained a small embryo compared with mature seed. At this early stage of seed development, sheep ingesting leafy spurge capsules have a very low potential to spread viable seed. Wicks and Derscheid (1964) found that leafy spurge seed less than 13 days old does not germinate.

More seed was excreted by ewes in 1993 than in 1994. Presumably, this is related to the greater seed production in 1993, which reflects the abnormally high precipitation during spring and summer. Surprisingly, the proportion of viable seed produced was lower in 1993 than in 1994, indicating that seed quantity and quality can be inversely related. In 1993, the seeds may not have matured fully. Besides normally high precipitation, temperatures were cool during the summer of 1993 and seed could have developed more slowly. On the other hand, the differences could simply reflect the differences in how fecal samples were processed. They were dried in 1993, then seed was recovered several months later by rewetting the samples. In 1994, seeds were recovered from fresh, moist feces.

The amount of seed excreted in the feces of naive and experienced sheep was similar. This indicates that these groups of sheep were consuming similar quantities of seeds. In a 3 year (1992–1994) study on grazing behavior of these same sheep, both groups spent similar amounts of time grazing leafy spurge, and

The amount of seed excreted in the feces of naive and experienced sheep was similar. This indicates that these groups of sheep were consuming similar quantities of seeds. In a 3 year (1992–1994) study on grazing behavior of these same sheep, both groups spent similar amounts of time grazing leafy spurge, and

had similar biting rates of this species in mid- and late summer (Olson et al., 1996). The estimated number of seeds excreted peaked at 144 in 1993 and 40 in 1994. In another field study, about 170 seeds of another forb, *Echium plantagineum* L., were excreted daily per sheep; germination of this seed was reduced by digestion (Piggin 1978). Based on a controlled dosing study, germination of leafy spurge seed is also reduced by passing through sheep and goats (Lacey et al. 1992).

In early July 1993 and the summer of 1994, seed excreted in feces was low on the first collection date within a period, increased on the second collection date, and then was low again on the final collection date. On the first collection date, the low number could reflect that the sheep had just left a paddock in which they had removed most of the seedheads shortly after they entered that paddock. On the second collection date, high numbers of excreted seed could reflect high consumption as they entered that fresh paddock. Most seeds of leafy spurge pass through sheep within 3-4 days (Lacey et al. 1992). On the third collection date, the low number could reflect that many of the available seeds had been consumed earlier, and had already passed through the digestive tract.

During both summers, seed that passed through sheep was less viable than seed collected in the field. Passing through the gastrointestinal tract of sheep, seed is constantly exposed to a warm, moist environment including microbial and enzymatic digestion. Apparently, one or more of these factors reduces viability of leafy spurge seed. Lacey et al. (1992) found that leafy spurge seed that was pulse-dosed to sheep was not viable after 4 days residence in the gastrointestinal tract. Whereas sheep digestion reduces viability, some leafy spurge seed in feces collected in our field study was viable. For a plant considered noxious such as leafy spurge, this would be undesirable if sheep are moved from infested to noninfested areas unless the animals are confined for at least 5 days (Lacey et al. 1992).

**Fig. 4. Estimated number of viable leafy spurge seeds excreted daily per animal in a. 1993 and b. 1994.**

**Conclusion**

Sheep grazing leafy spurge infested rangeland pick up seed in their fleece. We did not trace the path of this embedded seed, however it is unlikely that this seed will fall out on site. On the other hand, seeds that are consumed and passed through the digestive tract may enhance the dispersal of leafy spurge. Land managers using sheep to graze leafy spurge are advised to graze leafy spurge so that it does not flower, or if it does set seed, to not move sheep from infested to noninfested areas unless the animals are confined for at least 5 days (Lacey et al. 1992).
