Grazing effects on spring ecosystem vegetation of California's hardwood rangelands

BARBARA ALLEN-DIAZ AND RANDALL D. JACKSON

J. Range Manage. 53:215–220 March 2000

Abstract

Three watersheds at the University of California's Sierra Foothill Research and Extension Center (SFREC), Marysville, Calif. were selected to study cattle grazing effects on the vegetation surrounding cold-water springs and their downslope creeks. Three spring-creek systems from each of 3 watersheds were randomly assigned to grazing treatments (9 total). Treatments were ungrazed, lightly grazed (1,500 kg ha⁻¹ residual dry matter), and moderately grazed (1,000 kg ha⁻¹ residual dry matter) based on degree of use in upland pastures encircling the spring-creek systems. Total herbaceous cover at springs varied significantly among the 6 years only once (greater in 1994 than all others) covarying with previous year's rainfall. Grazing intensity did not affect total herbaceous cover at springs. A year X grazing treatment interaction (P<0.05) was detected for total herbaceous cover at spring-fed creeks. Three years after grazing removal, total herbaceous cover on ungrazed creek plots surpassed cover at moderately grazed and lightly grazed plots. Moderately grazed plot herbaceous cover declined steadily throughout the first 3 years, while lightly grazed cover remained relatively stable. Plant community composition and stability by year and grazing treatment were analyzed with TWINSPAN. With few exceptions, stable plant communities persisted on sites regardless of grazing intensity or cover changes. Total herbaceous cover was sensitive to interannual fluctuations, especially under increased grazing intensities. This attribute renders cover a more useful gauge of ecosystem health than plant composition as the latter may not provide evidence of potentially deleterious grazing X climate interactions until after soil erosion or water table characteristics are seriously, perhaps permanently, altered.

Key Words: Riparian, creek, cover, grazing, species composition

Manuscript accepted 10 July 1999.

The ecology and management of California's annual grasslands, woodlands, and savannas have been well studied (Bartolome and Standiford 1992, Bartolome and McClaran 1992, Bartolome et al. 1994, Heady et al. 1992, Standiford et al. 1997). However, few studies examine cold-water spring ecosystems of these rangelands, or the potential for grazing effects on them (Allen-Diaz et al. 1998).

Managers assess range condition or health by comparing existing plant community composition to a standard (Dyksterhuis 1949, Busby et al. 1994). Plant species cover is the variable most often estimated for generating range condition classes. Although grazing management changes often effect changes in vegetation cover, Bartolome (1984) and Milchunas and Lauenroth (1993)

Resumen

Se seleccionaron tres cuencas hidrológicas de la Estación de Investigación y Extensión Sierra Foothills de la Universidad de California con el objetivo de estudiar los efectos del apacentamiento del ganado en la vegetación circundante de manantiales de agua fría y sus arroyos pendiente abajo. En cada cuenca, tres sistemas de manantial-arroyos se asignaron aleatoriamente a los tratamientos de apacentamiento (9 en total). Los tratamientos fueron: sin apacentamiento, apacentamiento ligeramente (1,500 kg ha⁻¹ de materia seca residual) y apacentamiento moderadamente (1,000 kg ha⁻¹ de materia seca residual), los tratamientos se basaron en el grado de utilización de tierras arriba que circundan los sistemas de manantial-arroyos. La cobertura total de la vegetación herbácea en los manantiales varió significativamente solo una vez en 6 años (en 1994 fue mayor que los otros años) y los cambios se correlacionaron con la precipitación del año anterior. La intensidad de apacentamiento no afecta la cobertura total de la vegetación herbácea de los manantiales. En la variable cobertura total de la vegetación herbácea de los manantiales-arroyo, se detectó una interacción año x tratamiento de apacentamiento (P<0.05). Después de 3 años de que el apacentamiento se suspendió, la cobertura total herbácea de las parcelas de los arroyos sin apacentar superó a la cobertura registrada en las parcelas con apacentamiento ligero y moderado. La cobertura de herbáceas de las parcelas con apacentamiento moderado disminuyó paulatinamente durante los primeros tres años, mientras que la cobertura de las parcelas con apacentamiento ligero permaneció relativamente estable. La composición y estabilidad de la comunidad vegetal por año y tratamiento de apacentamiento se analizaron con TWINSPAN. Con pocas excepciones, comunidades estables de plantas persistieron en los sitios, independientemente de la intensidad de apacentamiento o los cambios de cobertura. La cobertura total herbácea fue sensible a las fluctuaciones interanuales, especialmente bajo las mayores intensidades de apacentamiento. Este atributo, en comparación con la composición de la comunidad, representa una mejor medida de la salud del ecosistema que este último puede no proveer de evidencia del daño potencial de la interacción apacentamiento x clima hasta que la erosión del suelo o las características de agua freática son seriamente alteradas.

suggested that species composition does not necessarily track cover variability and may lead to erroneous conclusions concerning long-term ecosystem productivity. Busby and Cox (1994) suggested that soil degradation and water quality parameters may be more important than plant species composition for assessing ecosystem health.

We tested the effects of different cattle grazing intensities on vegetation surrounding springs over 6 years on California’s oak-dominated hardwood rangeland. We hypothesized that reduced grazing intensity would induce plant community composition change. However, we held no a priori notions regarding compositional change direction.

**Study Site**

Research was conducted at Sierra Foothill Research and Extension Center (SFREC). The study site was described in detail in Allen-Diaz et al. 1998. Briefly, SFREC has an average annual precipitation of 72 cm•yr⁻¹. Air temperatures in the region range from monthly averages of 32.0°C in July to 2.2°C in January. Dominant vegetation is blue oak (*Quercus douglasii* Hook. & Arn.), yellow-bellied madrone (*Arbutus menziesii* Pursh) gray pine (*Pinus sabiniana* Douglas) woodlands and savannas with introduced annual grass and forb understories. Soils in this area are classified as Auburn (loamy, oxidic, thermic, Ruptic-Lithic Xerofrutes) and Argonaun (fine, mixed, thermic Mollic Haploxeralfs) series (Herbert and Begg 1969).

As described previously, springs and their resultant creeks are quite small (about 0.5 m wide at the source). Wetland species (Table 1 for typical spring spp.) remain green in summer and sharply delineate a spring’s boundaries, which extend an average of 3 m perpendicular to flow, forming oval-like borders. The highly palatable, perennial vegetation of spring ecosystems encourages intense cattle use. This is especially evident during summer months as upland annual grasses dry (Table 1 for typical annual grassland spp.). Concentrated utilization of springs creates visually striking vegetation impacts that motivated this study.

Three spring-creek systems were selected from each of 3 SFREC watersheds (Campbell, Schubert, and Forbes) for grazing treatment application (Allen-Diaz et al. 1998). Watersheds were selected for the presence of undeveloped springs, geographic proximity, and similar management histories. These watersheds had all been grazed by cattle at a moderate level (800 to 1000 kg•ha⁻¹ residual dry matter) since 1960 when the ranch came under University of California ownership. Prior to this ownership change, it is believed that greater livestock use levels existed (Kinney 1996), however, these use levels have not been quantified. Impediments to wildlife herbivory do not exist, nor do we believe any ever have in the past.

**Methods**

**Grazing treatment**

Each pasture within a watershed was randomly assigned a grazing treatment, ungrazed (UG), lightly grazed (LG), or moderately grazed (MG); applied from 1993 through 1997. The approximately 2 ha pastures were grazed by cattle following autumn germination (usually November). Cattle were then removed for the winter and returned to pastures during the spring season annual vegetation rapid-growth phase (February through April). Residual herbage on a dry matter basis (RDM) estimates were then made and cattle were returned to pastures in May to meet target RDM levels (Table 2 for annual RDM estimates). The number of animals placed in a pasture during any period was variable as it was based on available upland forage. Indeed, more animals were often placed on the lightly grazed plots because of site and interannual productivity differences (Allen-Diaz et al. 1998).

1No known common name
Cattle were English-cross yearlings, including Angus, Red Angus, and Hereford breeds that averaged 455 kg (Table 3). Actual use data for pastures surrounding springs were provided in Allen-Diaz et al. (1998). Livestock were managed under a comprehensive SFREC health care program, which included immunization against locally common cattle diseases several times annually.

Livestock grazing during the growing season has little effect on forage composition or productivity on California’s hardwood rangelands (Bartolome and McClaran 1992). Grazed California annual grass rangelands are managed so that target residual dry matter levels are achieved at the end of the annual grass growing season (late May) or before the new rains start (September) (Bartolome et al. 1980, Heady et al. 1992). Domestic grazing animals are generally allowed to graze rangeland pastures on a semi-continuous or periodic rotational basis so that at the end of the growing season RDM target levels for the grassland are met. Animal management objectives include maintaining or enhancing body weight, and animal numbers are adjusted depending on the quality and quantity of forage available at any time during the annual grass growth cycle. Other elements of the rangeland landscape, such as springs, are not managed for per se. Rather, these ecosystems experience cattle use levels in proportion to their desirability as green forage and place of water.

Experienced Research Center annual grassland range managers monitored grazing treatment intensity during each treatment period. Cattle were left on a site until a visually estimated residual dry matter (RDM) target level was attained during any grazing period. To quantify grazing treatment levels, upland RDM was measured annually (June) by comparing aboveground herbaceous biomass from 3 randomly-located 0.0625-m² clipped quadrats per treatment pasture.

**Vegetation sampling**

Depending on physical constraints imposed on transect length, a permanent 10-m or 5-m vegetation sampling transect was randomly established on each side of a spring and each side of a creek at each cohort in 1992 and was sampled annually in spring through 1997. Species cover was also estimated quasi-weekly 6 times from 11 April 1997 to 1 June 1997 to examine within-season variability. Transects were run parallel to spring or creek flow. The line-point method (Heady et al. 1959) was used to determine plant species cover 3 weeks after late spring (late May) cattle removal from grazing treatments. Vegetative “hits” were determined according to the first foliar intercept in the herbaceous layer. Total herbaceous cover was calculated as total hits minus non-vegetation hits divided by total hits. Plant species identification and nomenclature followed the Jepson Manual (Hickman 1993).

**Statistical analyses**

Potential differences in total herbaceous cover at springs and creeks among grazing treatments were assessed with split-plot, repeated measures ANOVA (S-PLUS 1993). Three watersheds comprised a blocking variable that effectively reduced error variance by partitioning site-to-site variability out of the ANOVA model. Each watershed was subjected to 3 grazing treatment levels (whole plot) repeatedly measured over 6 years (and 6 weeks for 1997; split plot). Homoscedasticity was verified for both factors but significant covariance among years indicated non-independence across factor levels rendering univariate analyses inappropriate for significance tests of temporal variation (Winer 1971). Hence, MANOVA was performed on year-wise orthogonal contrasts of total cover for tests of time. Orthogonal contrasts were created by multiplying total cover by a coefficient matrix whose determinant equaled zero. MANOVA was then performed using yearly responses as dependent variables (Venables and Ripley 1997). When significant main or interaction effects were detected, pooled standard errors of the differences among means were examined to ascertain which treatment levels gave rise to significant differences main or interaction effects.

Temporal changes in plant species composition across grazing treatments were assessed with TWINSPLAN, a divisive, polythetic classification program (Hill 1979). Default cut-levels were used to classify each pasture-year combination.

**Results**

Grazing treatments did not affect herbaceous cover at springs. Interannual variation was significant only in 1994, when total herbaceous cover was greater than cover totals in 1995 and 1997 (P < 0.05).

*adjustment to reach RDM standards
**7 bulls for 2 days on Campbell LG
Precipitation well above average in the 1992/93 rain-year coupled with below average precipitation for the 1993/94 rain year probably contributed to increased cover in 1994 and reduced cover in 1995 (Fig. 1).

A significant grazing X year interaction was determined for total herbaceous cover at creek sites (P < 0.05). Grazing treatment groups did not differ significantly for 1992 and 1993 (Fig. 2). But, in 1994, ungrazed (UG) cover increased dramatically from 63% to 86% while the moderately grazed (MG) group declined from 74% to 59% total herbaceous cover. The UG group retained greater cover than MG and lightly grazed (LG) in 1995 and 1996, but not in 1997. The LG group maintained the most stable total herbaceous cover values over the study period ranging between 45–55%. The MG group cover ranged from 80% at the beginning of the study (1992) to 34% one year after the lowest rainfall year (1994).

TWINSPAN classification analysis showed that only one spring transitioned to a new community type, a result of *Rubus* spp. expansion at the Forbes moderately grazed (MG) spring plot (Fig. 3). The transition occurred between 1992 and 1993 and has an associated eigenvalue (λ) of 0.434 indicating a high goodness-of-split (Jongman et al. 1995). All other splits were based on dominant tree presence (*Salix* spp., λ = 0.556), *Typha angustifolia* L. presence (λ = 0.474), and *Rhamnus californica* Eschsch. presence (λ = 0.359), which changed little during the study.

Results based on 1997 quasi-weekly sampling showed no grazing treatment effects and no temporal variation in total herbaceous cover at springs. A year X grazing interaction for total herbaceous cover at creeks (P < 0.01) reflected a difference between LG and MG for the initial 1997 sampling week (11 April). Lightly grazed and MG groups then stabilized at ~50% herbaceous cover for the remainder of the 1997 6-week sampling period. The TWINSPAN results showed no compositional changes over the 6-week sampling period.

Discussion

Domestic livestock have grazed the Sierra Foothill Research & Extension Center (SFREC) area for about 120 years. Although grazing intensity has certainly varied during this period, springs and their resulting creeks likely experienced periods of intense utilization, especially during summer. With the introduction of SFREC range management (1960), use at springs remained concentrated but less continuous, allowing for vegetative recovery and regrowth of perennial vegetation during rest periods. At SFREC, cattle are moved often, usually dictated by research needs.

While mean residual dry matter (RDM) target levels were met for the 6-year period, moderate- and light-grazed targets were transposed in several years (Table 2). This resulted from difficulties in reconciling visual upland RDM estimates with visual observations of spring use and because the presence of particular species at certain sites (*Typha angustifolia* L., *Rhamnus californica* Eschsch.) somewhat physically deterred riparian use until surrounding annual grasses had been heavily utilized. Moderately grazed and lightly grazed (LG) targets were also occasionally transposed because of upland vegetation regrowth under more favorable weather conditions after animals had been removed. Hence, cattle were sometimes removed from pastures before upland RDM targets were met. We do not believe that the minor interannual differences in RDM target levels affected the overall 6-year results.

In fact, our study continued the 120-year history of periodic, intense use of the spring systems at both LG and moderately grazed (MG) treatment levels, but especially at MG levels. The ungrazed (UG) treatment can be thought of as release from 120 years of MG use. Grazing treatments, including complete protection, did
Fig. 3. TWINSPAN classification results. Roman numerals indicate different division levels. Numbers in shaded boxes indicate year, first letter denotes watershed (F=Forbes, S=Schubert, C=Campbell), second letter denotes grazing treatment (M=moderately grazed, L=lightly grazed, U=ungrazed), "Sp" denotes spring-site, "Cr" denotes creek-site. Classification divisions were based on presence (+) or absence (-) of noted species. Strength of a given division is measured by eigenvalue (\( \chi^2 \); 0.00-1.00 range).

not alter total herbaceous cover at springs or species composition at springs or creeks during the 6-year study.

The finding that MG plots changed in total cover more among years at creeks and springs than either the LG or UG groups, possibly under the influence of rainfall fluctuations, is compelling. Annual rainfall patterns control variations in species dominance on California’s annual grasslands (Pitt and Heady 1978). It appears that these same patterns could similarly influence herbaceous cover in the perennial vegetation of low-flow spring systems, but with a 1-year time lag (Fig. 1). We did not observe interannual rainfall induced shifts in vegetation composition, an anticipated result, because seed bank, edaphic characteristics, and water, which are known to affect annual uplands, are less limiting at spring ecosystems.

We speculate that prolonged drought in moderately grazed situations probably reduces herbaceous cover at both springs and creeks, but without an immediate impact on plant community composition until some low-cover threshold is crossed (sensu Bartolome 1984). We hypothesize that soil loss and decreasing water table depth would eventually produce compositional changes on moderately grazed systems, given drought conditions. As spring flows seasonally waned, the changing pattern of water table drawdown shown to affect composition in wet meadows (Allen-Diaz 1991) should eventually induce compositional transitions. Shallow-rooted annual species would move into formerly saturated areas. It is unknown whether these changes would be fluid enough that a return to pre-drought spring flow would result in a linear, reverse transition to pre-drought species composition and spatial extent. However, given that this system has been moderately grazed for 120+ years, enduring several droughts, it seems apparent that the plant communities found presently represent some relatively stable result of Mediterranean-type climatic regimes. Monitoring to detect threshold response of these spring-creek systems under continued grazing exclusion and increased grazing intensity (target ~600 kg·ha\(^{-1}\) RDM) will continue.

Instead of showing more sensitivity to grazing, ample water supply seems to buffer deleterious grazing effects at springs and spring-fed creeks. This buffering apparently stabilizes perennial spring vegetation composition. We conclude that species composition is not sensitive to existing grazing systems that include periodic intense use coupled with overall moderate grazing levels on uplands. Instead, spring vegetation composition appears resistant to changes in both grazing and climatic conditions.

However, total vegetative cover appears to be a more useful metric for abiotic and biotic resource conservation in these systems. We base this conclusion on our finding that total herbaceous cover is sensitive to weather variability, especially under higher grazing intensities. Because total cover is directly linked to erosion rates and hydrologic processes (Busby et al. 1994, Busby and Cox 1994), total cover may prove to be an appropriate monitoring parameter for these systems.
