Water holding capacity of litter and soil organic matter in mixed prairie and fescue grassland ecosystems of Alberta

M.A. NAETH, A.W. BAILEY, D.S. CHANASYK, AND D.J. PLUTH

Abstract

Litter and organic matter accumulations can reduce soil water through interception of precipitation and subsequent evaporation of absorbed water. Interception varies with mass and water holding capacity (WHC) of litter and organic matter, and is highest from small precipitation events. WHC varies with vegetation type, which is affected by grazing regime. Thus long-term grazing could affect WHC of litter and organic matter and would be important in the hydrologic assessment of rangelands subjected to many small precipitation events throughout the growing season.

The study was conducted in mixed prairie, parkland fescue, and foothills fescue grasslands in Alberta, Canada. Grazing regimes were of light to very heavy intensities, grazed early, late, and continuously during the growing season. Litter and organic matter were sorted by sieving into various sized categories. Litter-soil cores were also evaluated.

WHC of litter and organic matter was lower in mixed prairie than in fescue grasslands. WHC increased with increased particle size, being higher for roots and standing and fallen litter than for organic matter. WHC of large particle-sized material decreased with heavy intensity and/or early season grazing. WHC was affected more by intensity than season of grazing. Grazing affected WHC through species composition changes, since species have different WHC, and through trampling which affected particle size. It was concluded that litter and organic matter WHC were important in rangeland hydrologic assessments.

Key Words: interception, grazing intensity, field capacity, rangeland hydrology

Litter can reduce the amount of water reaching the soil surface through interception of precipitation and subsequent evaporation of absorbed water. Interception losses from small storms are generally high while those from larger storms are under 10% (Corbett and Crouse 1968).Thurow et al. (1987) reported interception losses by mixed prairie grasses at 14 to 24%. The amount of water subsequently evaporated is governed primarily by the mass of accumulated litter (Helvey and Patric 1965), water holding capacity (WHC) of litter, and evaporation potential before and after the precipitation event (Corbett and Crouse 1968). WHC of litter varies with vegetation type, with that of litter in grasslands ranging from 0.5 to 8.4 mm (Flory 1936, Weaver and Rowland 1952, Burgy and Pomeroy 1958, Corbett and Crouse 1968). Thurow et al. (1987) reported WHC of 114% for curlymesquite and 81% for sideoats grama in Texas.

Grazing regimes facilitating accumulation of litter and organic matter could reduce mineral soil water due to retention of precipitation above-ground and subsequent evaporative loss. However the increased infiltration capacity and reduced evaporation from the soil surface from such accumulations and the reductions in evapotranspiration due to defoliation from grazing will generally more than offset this (Lowdermilk 1930, Weaver and Rowland 1952). In rangelands of the Northern Great Plains where many small precipitation events occur throughout the growing season, precipitation not contributing to soil water because it was intercepted and evaporated could be significant. It was hypothesized that WHC of litter and organic matter would be affected by its particle size distribution and thus grazing regimes facilitating accumulation of litter or organic matter of sizes which had high water holding capacities would reduce soil water the most. It was further hypothesized that overall water holding capacity would differ with ecosystem as affected by plant species composition.

If long-term grazing affects WHC of litter and organic matter and leads to reductions in soil water, these reductions will be important in the hydrologic assessment of rangelands subjected to many small precipitation events throughout the growing season and should be considered in management and modelling. Thus a study was initiated in mixed prairie and fescue grasslands of Alberta, Canada, with the objectives (1) to determine whether WHC of litter and organic matter is affected by ecosystem, (2) to determine whether particle size of litter and organic matter affected WHC, and (3) to determine the effect of season and intensity of grazing on WHC of litter and organic matter.

Materials and Methods

Study Sites

Three study sites representing major rangeland ecosystems of southern and central Alberta were selected. Each site had long-term grazing treatments, ungrazed controls, grass-dominated vegetation that had never been cultivated, and slopes of less than 2% (Naeth 1988).

The mixed prairie site was located near Brooks approximately 225 km east of Calgary (51° N and 112° W). The area has a continental prairie climate and a semiarid moisture regime. Mean annual precipitation is 355 mm. Mean annual temperature is 4° C, with a July mean of 19° C and a January mean of –14° C. Elevation averages 745 m above sea level with slopes of less than 2%. Soils are Brown Solidized Solonetz and Brown Solod (Natirboroll) deve-
loped on till (Kjærsgaard et al. 1982). Vegetation is of the Blue grama-Spear grass-Wheat grass (Bouteloua-Stipa-Agropyron) faci-
cation, dominated by blue grama grass (Bouteloua gracilis Lag.), spear grases (Stipa comata Trin. & Rupr.), and western and northern wheatgrasses (Agropyron smithii Rydb. and dasystachyum Hook.). Pasture sage (Artemisia frigida Willd.) and little clmboss (Setonigetia densa Rydb.) are common forbs. A short grass
disclimax dominated by blue grama is common as a result of heavy
term grassing.

The parkland fescue site was located near Kinsella approximately
150 km southeast of Edmonton (53° N and 111° W). The climate is dry subhumid. Mean annual precipitation is 422 mm. Mean
amnual temperature is 2°C with a July mean of 17°C and a
January mean of -17°C. Elevation averages 685 m above sea level
with gently rolling to hilly topography (Howitt 1988). Grassland
soils are dominated by Orthic Black Chernozems (Clyobotoroll)
developed on till. Vegetation consists of grass and shrub communities
ttir with aspen groves occurring at irregular intervals. Rough
fescue (Festuca hallii Vasey Piper) (Pavlick and Looman 1984)
domains open undisturbed grasslands and western porcupine grass
(Stipa curitseta Hitchc.) co-dominates on grazed areas. Forbs are a common component of the vegetation.

The foothills fescue grassland site was located near Stavely approximately 100 km south-southwest of Calgary (50° N and 114° W). The
climate is subhumid without marked deficiency of precipitation. Mean annual precipitation is 550 mm. Mean annual
temperature is 5°C, with a July mean of 18°C and a January mean of
-10°C. Elevation averages 1,350 m above sea level and topo-
graphy is gently rolling to hilly. Soils are Orthic Black Chernozems
(Haploboroll) developed on till (Johnston et al. 1971). Vegetation
is of the fescue grassland association with rough fescue (Festuca campestris Rydb.) dominating in the undisturbed and lightly
grazed areas. Parry’s oat grass (Danthonia parryi Scribn.) and bluebunch fescue (Festuca idahoensis Elmer) are co-dominants in
grazed areas. Under heavy grazing regimes, rough fescue is replaced by annual invaders and bluegras (Poa L.) species.

Grazing Treatments
In mixed prairie, 3 grazing treatments were studied within a
community pasture established in 1964: (1) early season grazing
from May through July; (2) late season grazing from August
through October; and (3) a control ungrazed since the late 1930s.
The stocking rate was heavy at 0.9 AUM ha⁻¹.

In parkland fescue, 5 grazing treatments established in 1973 on
the University of Alberta ranch were studied: (1) light June grazing
from 1 to 30 June at 1.5 AUM ha⁻¹; (2) heavy June grazing from 1
to 30 June at 4.4 AUM ha⁻¹; (3) heavy autumn grazing from
15 September to 15 October at 4.4 AUM ha⁻¹; (4) light autumn
grazing from 15 September to 15 October at 1.5 AUM ha⁻¹; and (5)
a control ungrazed since 1942 (Bailey et al. 1987).

In foothills fescue, 5 grazing treatments established in 1949 on
the Agriculture Canada Range Research Substation and grazed
May through September were studied: (1) very heavy grazing at 4.8
AUM ha⁻¹; (2) heavy grazing at 2.4 AUM ha⁻¹; (3) moderate
grazing at 1.6 AUM ha⁻¹; (4) light grazing at 1.2 AUM ha⁻¹; and (5)
a control comprised of permanent enclosures in each treatment
(Johnston et al. 1971).

Experimental Design and Statistical Analyses
The experimental design within each site had a hierarchical
arrangement of grazing treatment, sample area, and subsamples
(Steel and Torrie 1980). Three 0.1-ha sample areas were randomly
established within each treatment.

Statistical analyses were conducted using variation among the
0.1-ha sample areas as a measure of error for testing the significance
of treatments. Data were tested for homogeneity of variance using
Cochran and Bartlett-Box tests. The W test was used to test data
for normality of distribution (Shapiro and Wilk 1965). Analysis of
variance was used to test for treatment effects. Data with signifi-
cant F values were further analyzed to separate the means using the
Student-Newman-Keul (SNK) test at the 5% probability level
(Steel and Torrie 1980).

In each year by treatment combination, variation among sam-
ples was not significantly different from subsamples and, therefore,
sample and subsample variation were pooled in further analyses.
There was no significant difference within a treatment between study years so data from both years were pooled. Sources of
variation in the final statistical analysis were treatments and error
within treatments.

Sampling and Analyses
For this study, litter refers to all dead organic material not
incorporated with mineral soil and occurring above soil mineral
horizons. Soil organic matter refers to the organic fraction of soil
( Canada Department of Agriculture 1979).

At each site, sampling was conducted in late August 1985 and
1986 using 10 randomly located 0.1-m² quadrats in each sample
area (30 per treatment). Live vegetation, including dried tips of live
plants, and standing litter were removed with clippers at ground
level. Fallen litter was removed from the soil surface with hand
rakes. Soil organic matter was lifted as a slab, after cutting down to
a mineral soil horizon where color and textural changes were used
to locate the bottom of the Ah horizon. Sampling depths averaged
5 to 8 cm in mixed prairie (no difference in depth among treat-
ments) and 10 to 15 cm in parkland fescue (no difference in depth
among treatments) and foothills fescue (very heavy grazing shall-
ower than other treatments).

Live vegetative material was oven dried at 65°C for 24 hours,
then weighed. Litter and organic matter samples were air dried
then sorted by size using sieves mounted on an automatic sieve
shaker as modified from Coupland (1973). Five minutes of shaking
was required to sort the samples without breaking down plant
material. Sieves selected on the basis of laboratory trials had
openings of 2.0, 0.85, and 0.212 mm (9, 20, and 65 mesh Tyler
equivalents), with a bottom pan.

The litter and soil organic matter were separated into 6 catego-
ries: (1) standing litter collected in the field; (2) coarse litter remain-
ing in the top sieve (2 mm) and recognizable as undecomposed
plant parts; (3) medium litter that was partly decomposed and
collected in the second sieve (0.85 mm); (4) fine organic matter that
was relatively decomposed and collected in the third sieve (0.212
mm); (5) very fine organic matter that was decomposed and col-
lected in the bottom pan; and (6) roots visibly greater than 0.2 mm
which were removed from the above samples. Categories 4 and 5
contained most smaller roots and root hairs. Above-ground
organic matter comprised standing, coarse, and medium litter, and
live vegetation. Below-ground organic matter comprised roots,
and fine and very fine organic matter. Total organic matter
included all above categories.

In 1985 and 1986, 9 soil and litter samples to a depth of 76 mm
were taken from each treatment with a 76 mm diameter Uhland
core sampler. The top of the core corresponded to the top of the
fallen litter layer. These cores were used to determine WHC of litter
and organic matter in a relatively undisturbed state and thus a truer
reflection of treatment effect.

Determination of Water Holding Capacity
Water holding capacity (WHC) of litter and soil organic matter
was determined with modifications to methods outlined by Kit-
tredge (1955) and Bernard (1963). After sorting of the samples
collected each year, 5 randomly selected samples from each litter
and soil organic matter category from each 0.1-ha sample area was

14 JOURNAL OF RANGE MANAGEMENT 44(1), January 1991
used to fill 7 cm high by 7 cm diameter plastic cylinders to a standard weight (15 per treatment). Cotton fabric secured with a rubber band was used to cover the cylinder bottom. Cylinders were saturated for 48 hours in a sink and then placed on a tray of damp sand to drain for 48 hours.

The sand mixture used for drainage was 11% gravel, 23% very coarse sand, 38% coarse sand, 22% medium sand, and 6% fine and very fine sand as determined by dry sieving (McKeague 1978). Prior to samples being placed on it, the sand was put in a large plastic tray with a drainage spout for water, saturated with water and drained for 48 hours. Water content of sand at the time litter and organic matter samples were placed on it was 10.8% (SD 2.1%). After the cylinders drained for 48 hours, water content of the sand was 14.0% (SD 2.4%). Laboratory temperature was maintained at approximately 18°C and relative humidity at approximately 35%. Trays were covered with plastic to prevent evaporation and create a stable microenvironment.

After draining on the sand, the samples were weighed and oven dried at 105°C for 48 hours then re-weighed. Water holding capacity for each sample was determined by subtracting oven dry mass of its cylinder contents from its drained mass, dividing by oven mass, and multiplying by 100 (g water/g litter (o.d.w.) x 100 = % WHC). Uhland core samples were treated in the same manner.

**Results**

Within a treatment, WHC of litter and soil organic matter did not generally differ significantly with year, and plotted data are means of years. At all 3 sites, WHC of roots, standing litter, and coarse organic matter were higher than that of medium, fine, and very fine organic matter (Figs. 1, 2, and 3). WHC was generally higher in fine than in medium or very fine organic matter.

WHC of mixed prairie roots, standing litter, and coarse organic matter ranged from 172 to 216% and that of fine, medium, and very fine organic matter from 68 to 148% of oven dry weight (Fig. 1). In parkland fescue, WHC of roots, standing litter, and coarse organic matter ranged from 180 to 258% and that of medium, fine, and very fine organic matter ranged from 78 to 148% (Fig. 2). In foothills fescue, WHC of roots, standing litter, coarse, and fine organic matter ranged from 200 to 254%, while that of medium and very fine organic matter ranged from 107 to 139% (Fig. 3).

WHC of undisturbed cores was affected more by intensity of grazing than by season of grazing (Table 1). In both tescue grasslands, WHC of cores was lower in heavy and very heavy treatments than in control or moderate treatments. In mixed prairie WHC did not differ significantly with treatment. WHC was highest in foothills fescue and lowest in mixed prairie.

hydrophobicity when wetting the litter and organic matter. Organic substances adsorbed on mineral particles were reported to confer hydrophobic properties on mineral soils (Debano and Letey 1969), reducing WHC.

**Discussion**

WHC of roots, standing litter, and coarse organic matter were higher than those of medium, fine, and very fine organic matter because of larger amounts of material in a relatively undecomposed state in these former fractions. This is best explained by the work of Farmer (1978), who reported that soil organic matter occurs in 2 forms: discrete, largely organic particles and a molecular form on mineral surfaces. At saturation, the large organic particles with a wide range of pores hold up to twice as much water per volume as mineral soils. More highly decomposed organic matter of the molecular form would hold less water due to less pore space and adhesion in molecular form. Although very fine organic particles would have a greater surface area than larger particles and therefore hold more water, the higher porosity of the larger particles tends to offset this. The higher WHC of fine organic matter compared to medium and very fine organic matter is also related to particle size. The fine organic matter category contains the majority of small roots and root hairs and is thus largely in a relatively undecomposed state, capable of holding more water than the largely molecular organic matter in the medium and very fine categories.

Grazing treatment effects on WHC reflect changes in species composition caused by grazing and the effect of treading on litter decomposition rate. Soil characteristics had less effect since there were no significant within-site soil textural differences (Naeth 1988). There were no significant differences in soil bulk density among cores in mixed prairie (Naeth 1988). Significant differences did occur in both fescue grasslands. However, resulting differences in soil porosity contributed only a small fraction to the resultant WHC compared to differences attributable to litter. WHC of litter varies with grassland vegetation (Flory 1936, Weaver and Rowland 1952, Burgoyne and Pomeroy 1955, Johnson and Crouse 1968) and there were major vegetation changes due to grazing in mixed prairie (Naeth 1985), parkland fescue (Bailey et al. 1987), and foothills fescue (Johnston 1961, Johnston et al. 1971). Since grazing effects on WHC occurred where the greatest species composition differences were found—the control and early season grazing in mixed prairie, the control and heavy grazing in parkland fescue, and the control and light grazing compared to heavy grazing in foothills fescue—it can be stated that grazing affects WHC of litter and organic matter. This is partly explained by different cellulose and lignin contents of different species resulting in different decomposition rates (Norman 1933). Higher WHC of organic matter in the control is in part due to the absence of trampling which can break litter into smaller pieces, create better litter-soil contact, and facilitate more rapid decomposition (McCalla 1943). Thus there will be more large particle-sized litter in the control contributing to higher WHC. Zeller (1963) also found higher amounts of decomposed litter than fresh litter in grazed grasslands.

WHC in this study represents maximum available storage and the upper limits for precipitation held in organic matter mass. Although some differences in WHC of individual litter and organic matter categories occurred among grazing treatments, the overall effect of grazing on WHC of litter and organic matter in mixed prairie is likely small, since differences in WHC of whole cores were not detected in any treatment. In the fescue grasslands, whole core values show WHC of organic matter generally declines with heavy intensity grazing. From a soil conservation perspective this may be contradictory in that light grazing, which improves overall hydrologic condition (Naeth 1988), can lead to accumulation of organic matter with higher WHC. However, the more beneficial effects of holding water as opposed to its running off the soil surface would tend to negate the higher WHC. Similar conclusions have been made by Lowdermilk (1930) and Weaver and Rowland (1952). The lack of significant grazing treatment effects on WHC of organic matter would indicate grazing treatment would not affect overall below-ground WHC. However, the higher WHC in the coarse litter in parkland fescue under light autumn grazing and in the control, and in the heavy grazing treatment in foothills fescue would indicate the above-ground litter would have the greatest effect on overall WHC. This is evidenced by the lower standing crop soil water contents in the controls than in the grazed treatments for the study sites (Naeth 1988).

McCalla (1944) found decreases in dry weight and volume of litter were accompanied by increases in wetting speed in initial decomposition stages, which combined with higher WHC of larger sized organic matter, would mean greater absorption of precipitation. Greater masses of large sized organic matter per unit land area and higher ground cover in control and light intensity grazing treatments (Naeth 1988) could lead to higher interception and retention than in heavy intensity grazing treatments.

Biomass and cover have also been identified as sources of variation in interception by Clark (1940) and Thurow et al. (1967). Thurow et al. (1987) hypothesized that pilose blades and horizontal growth form of curlymesquite aided water retention, compared to the relatively vertical smooth blades of sideoats grama, but this was offset by a lower standing crop production potential. Thus interception storage capacity was greater for sideoats grama-dominated grasslands than for curlymesquite dominated grasslands. Similarly such biomass and growth forms may affect actual field interception and WHC of litter and organic matter in grasslands from this study, with that of mixed prairie vegetation being lower than that of the 2 fescue grasslands.

**Conclusions**

1. WHC of litter and organic matter differed with ecosystem, being lower in mixed prairie than in fescue grasslands.
2. WHC differed with particle size of litter and organic matter. WHC of large particle-sized litter and organic matter was higher than that of small particle-sized litter and organic matter.
3. Grazing affected WHC of litter and organic matter with WHC in large particle-sized organic matter decreasing with heavy intensity and/or early season grazing, and WHC of small particle-sized organic matter being less affected by grazing treatment. WHC of undisturbed cores was affected more by intensity than season of grazing.
4. WHC of litter and organic matter, plant species composition, and amounts and kinds of organic matter are all key factors in determining the overall WHC of litter and soil organic matter layers in individual grasslands. WHC must be considered in hydrologic assessments and modelling of rangelands where small storms are a common form of precipitation since they may affect soil water especially in the near surface zone. The amount of large particle-sized organic matter relative to small particle-sized organic matter is a critical factor in determining the magnitude of WHC in the 3 grassland ecosystems examined.
