graze on these plants. Since most livestock intoxications by these plants are of a chronic nature, the plants can be grazed for short periods of time without damage being done. Those responsible for grazing livestock in areas infested with these Astragalus plants should be aware if their animals are eating milkvetch so that action can be taken before animals grazing these plants are poisoned.

Conservation Helps a Dry Creek Flow Again

Mark E. Moseley

A West Texas creek dry for decades started flowing again, and the residents of nearby San Angelo can thank ranchers and their conservation work in a 74,000-acre watershed. In the early 1960’s landowners on 5 ranches, covering about half the watershed, began rootplowing, reseeding, treedozing, aerial spraying, and chaining. The ranchers received technical assistance and cost-sharing for this work through the Great Plains Conservation Program. The program is administered through local Soil and Water Conservation Districts in selected Great Plains counties by USDA’s Soil Conservation Service. These ranchers did not start out to prove anything—it just happened.

West Rocky Creek flowed yearlong until the drought of 1918-1919, when it became an intermittent stream. By 1935, springs feeding the creek had been dried up by mesquite and other invading woody plants.

Located in the Edwards Plateau region, West Rocky Creek is a tributary of the Middle Concho about 20 miles west of San Angelo. Average annual precipitation is about 18 inches. Shallow soils formed over limestone and caliche are characteristic of the plateau regions, and early day travelers described the rough, rolling hills as barren. The only timber was along the draws and the need for firewood was a real concern to these pioneers.

Before the area was settled, prairie fires were common—set naturally by thunderstorms and also by Indians. Early travelers reported seeing prairie fires that would burn for miles prior to being extinguished by either a lack of fuel or by rainfall. Fires suppressed the brush. As the early pioneers began to fence the rangeland, several things triggered. Their apparent lack of understanding about grazing management depleted the cover of prairie grass such as sideoats grama, the state grass of Texas. In pristine condition, most of the watershed supported a plant cover averaging 2,000 pounds of production per acre—mostly grasses.

Settling of the land stopped the wildlife for 2 reasons—1— they fought the wildfires and 2—there was no longer enough grass to burn. This lack of ground cover allowed erosion to take place and left little water on the land. Not only did the reduced ground cover short circuit the aquifer recharge cycle but it provided a favorable environment for the establishment of brush plants. The brush first encroached the deeper soils and then gradually moved up the draws to the hillsides. The watershed now would support only about 500 pounds per acre of protective grasses.

Mesquite was the main brush problem. With its extensive root system it can draw water from far below the 5-foot depth that is generally the limit for native grasses such as sideoats grama, buffalograss, curly mesquite, and tobosa. Its thirst for water is much greater than that of the native grasses. In fact, it takes about 1,725 pounds of water to grow a pound of mesquite, but only 705 pounds of water to grow a pound of sideoats grama. It is interesting to note that scientists estimate that 38% of the rainfall in Texas is used up by non-economic plants. This equates to about 138 million acre feet per year. (Johnston 1957).

In 1964, following the accelerated range conservation program, one of the 5 ranchers noticed that a spring—dry since 1935—had started flowing again. By replacing the water-hungry brush with a good grass cover, more rainfall soaked into the aquifer, recharging the dormant springs. By 1970, springs had begun flowing on all 5 ranches. West Rocky Creek, which now flows at a rate of 475 to 4,000 gallons per minute is not big by most standards but its sparkling waters are a welcome sight in this part of Texas. All the conservation work was done in a manner that would benefit whitetailed deer and turkey—a valuable hunting resource.

The role of sound grazing management cannot be overlooked. The ongoing grazing management on each ranch enhances the cover of grasses on the watershed. The soils now, under good grazing management, are producing an estimated 2,000 - 2,500 pounds of forage per acre—still mostly grasses.

This grass cover retards the reinvasion of brush and helps hold water and soil on the land. The turf decreases the sediment load in surface water supplies. Sediments reduce water quality and the storage capacity of reservoirs and streams. Although the brush succession is retarded, these ranchers periodically must do maintenance brush work just to keep things in the desired balance.

Even though the rangeland improvements have reduced erosion in the watershed and increased forage production for the ranchers’ livestock, the story of the West Rocky Creek may be more important to the 70,000 residents of San

Selected Readings

Angelo. Water from the creek supplements the city's water supply reservoirs. Currently, water in San Angelo homes costs $3.05 for the first 2,000 gallons and $0.67 for each 1,000 gallons thereafter. The West Rocky Creek Watershed yields an estimated 525,600,000 gallons annually. If water costs are calculated at $1.50 per 1000 gallons, the West Rocky Creek Watershed yields $788,400 of clear water annually. In other words, each acre of the West Rocky Creek Watershed yields approximately $10.63 worth of water annually.

West Rocky Creek now contributes approximately 7% of San Angelo's total water needs. Its watershed occupies 3% of the entire watershed that supports the municipal and recreation supplies of San Angelo.

If the West Rocky Creek treatment were expanded to the entire watershed above San Angelo, one could predict a long lasting supply of clear water, increased livestock and wildlife production, and decreased sedimentation of downstream water supplies.
