Knapweeds: British Columbia’s Undesirable Aliens

R.M. Strang, K.M. Lindsay, R.S. Price

Introduction

Knapweeds were introduced into Canada from their native Eurasia in shipments of alfalfa seed about the turn of the century. Since growing conditions in the dry interior of British Columbia are very suitable for them, they are spreading vigorously, so vigorously that they pose a major threat to the rangelands and ranching industry of the Province.

It has been estimated (Harris and Cranston 1979) that knapweed infestation is now causing annual losses of range production worth $900,000; that it is increasing at about 10% a year in B.C.; and that 10,000 ha are susceptible to invasion in Western Canada. Parts of the U.S., especially Montana, are also seriously affected.

Location

Interior British Columbia is a steeply dissected, rolling plateau lying between the Coast Mountains to the west and the Columbia/Rockies chain to the east. The northern limits of the ranching area, at about Lat. 55°N, are the Skeena and Omenica Highlands. Lying in the rain shadow of the coastal mountains, the area is dry and fairly hot, with availability of soil moisture limiting growth, but local climate is strongly affected by elevation and aspect. Precipitation may be as low as 20 cm annually and frost-free days range from 180 to 110. Soils are chernozemic in the valley bottoms changing up-slope to luvisols or brunisols. Bluebunch wheatgrass is the climax dominant in the valley bottom grasslands; above this one finds open ponderosa pine/bunchgrass forest and, still higher or further north, Douglas-fir/pinegrass. These climax communities have been much changed by heavy grazing, logging and burning. They now constitute the ranching area of the Province, providing some 800,000 AUM’s of grazing each year.

Plant Characteristics

The knapweeds are members of the Centaureinae subtribe in the Compositae, the sunflower family. Diffuse knapweed (Centaurea diffusa L.), usually a biennial, grows rapidly in its second summer from an overwintering rosette form to a stalk about 80 cm with 70–80 white or occasionally purple flowerheads on each plant. Since 10–15 seeds are produced in each flowerhead, up to 1,000 seeds can develop on a single plant (Fig. 1). Spotted knapweed (C. maculosa L.) too, is mostly biennial but pro-

References

duces only half as many purple flowerheads (Fig. 2). Russian knapweed (C. repens L.) has also been introduced, but it is a relatively insignificant pest (Watson and Renney 1974). A fourth species, black knapweed (C. nigra L.), has also been noted but it is very limited in its distribution.

Knapweeds are pioneer species, taking hold quickly and thriving on disturbed dry sites but only rarely on burned areas. Diffuse knapweed is spread most commonly when the mature plant dies, breaks off at the rootstock, and is blown or carried away, to shed seed and give rise to a new population where the dry plant comes to rest. Individual seeds can easily become attached to passing animals and thus transported. Spotted knapweed, which grows in cooler, more moist sites than the diffuse species, spreads less dramatically, by flicking its dry seeds, called achenes, up to 1 m from the parent plant. It is also spread by birds, small mammals, and ants.

**Spread and Competition**

Spotted knapweed was recorded from Victoria in 1893 by the botanist and explorer Macoun. In 1907 it was reported in Klitekat County, Washington, and by 1930 it was known in B.C. at Pritchard and Lytton (Renney 1959). Within 20 years knapweeds were widespread in the Okanogan (sic) and were spreading in the Grand Forks and Cranbrook/Kimberley areas. By 1952 it was estimated (Watson and Renney 1974) that there were about 100 ha of diffuse and 120 ha of spotted knapweed in the Thompson and Nicola River catchments. These areas had increased to 26,000 and 3,400 ha respectively by 1974. Now, knapweeds are present as far north and west as Prince George and Tatlayoko Lakes. Harris and Cranston (1979) estimate that almost 11 million ha in western Canada have a soil and climatic environment into which knapweeds could easily spread and flourish if they are not controlled.

Animals only occasionally eat young plants and they avoid mature specimens, which are harsh and spiny. Thus, since it is not grazed, knapweed spreads at the expense of forage species. It has also been established (Fletcher 1961; Fletcher and Renney 1963) that once knapweeds have grown in a soil, that soil will for some time not support other species, amongst them at least one grass, barley. This inhibitory effect, called allelopathy, appears to be a second factor which contributes to reduction of forage production once knapweed has become established. Competition for available soil moisture probably also reduces forage yields.

Good bluebunch wheatgrass range in the Kamloops area of B.C. has an average annual production of up to 1,000 kg/ha when in excellent condition. When knapweeds are present, the yield may drop to as little as one tenth of this, or only 60 kg available forage per ha. Because of past mismanagement, not many ranges are in excellent condition; nevertheless, the loss of forage is substantial. Harris and Cranston (1979) put the average loss at $12/ha and the potential annual loss to B.C. and its ranching industry at $13 million if knapweeds spread to their limits.

**Containment and Control**

A two-pronged response has developed to this very serious problem. The first is a containment program, begun in 1969, to
Increase Forage Production
Plant PERMA-PEL
Range & Pasture Mixes

Depend on Ramsey Seed — long a leader in range improvement programs — for the finest clover, sub-clover, and grass seed mixes. Ramsey provides 3 general mixes for varying rainfall and soil conditions . . . plus special mixes for special situations. Introduce your range improvement program to Rhizo-Kote® and Nutri-Kote®. The seed coatings that provide a controlled germination zone, aids seedling establishment, and offers optimum rhizobia viability for root nodulation of legumes.

Write or phone for seed mix quotes (and for a free range seeding brochure)

Summary

From the time of their introduction about 1900 until now, the knapweeds, Centaurea spp., have spread vigorously to occupy at least 30,000 ha and to be present throughout the rangelands of interior B.C.

Reduction of forage production in the presence of knapweed is considerable, up to 90% in some instances, and so control measures are urgently required.

While a biological control program using natural predators introduced from the knapweed’s home habitat is being developed, a chemical containment program is in force in an effort to limit spread until biological control is effective. Picloram or Tordon 22K is being sprayed in peripheral areas of infestation to restrict further extension of areas of infestation. Allied to this chemical treatment, a program to generate better public understanding of the problem, its implications, and the role of the public in minimizing spread of knapweed is needed.
